Site of Neonatal Infection	Rate of Positive Cultures (%)	Population	Reference
Conjunctiva	0-10	Exposed infants who underwent silver nitrate ocular prophylaxis	Edwards et al, 1978[120] Allen and Barrere, 1949[4] Armstrong et al, 1976[11] Laga et al, 1989[207]
	2-48	Exposed infants who had no ocular prophylaxis	Rothenberg, 1979[294] Fransen et al, 1986[132] Laga et al, 1984[202]
Orogastric fluid	26-40	Infants of infected mothers	Handsfield et al, 1973[162] Edwards et al, 1978[120]
Oropharynx	35	Infants with gonococcal ophthalmia	Laga et al, 1989[207]
Disseminated disease as a proportion of all neonatal gonorrhea	0-1 (rare)	Reported series of neonatal gonococcal disease	Folland et al, 1977[130] Tomeh and Wilfert, 1973[339] Wald et al, 1980[348] Edwards et al, 1978[120] Fransen et al, 1986[132]

well as other likely pathogens, which include *Staphylococcus* spp., group B streptococci, *H. influenzae*, and gram-negative enteric flora. Herpes simplex also may be present in areas of injury to the scalp of newborns. Overall, approximately 1/200 births that are monitored with fetal scalp electrodes are complicated by infection at the monitoring site.[272]

Neonatal gonococcal vulvovaginitis, proctitis, rhinitis, funisitis, and urethritis have been described but are infrequent findings.[156] Gonococcal colonization of the oropharynx, gastric fluid, or both occurs relatively frequently in perinatally exposed infants, however. Pharyngeal colonization is present in as many as 35 percent of neonates who have GON.[132] A summary of selected studies on the incidence of neonatal gonococcal colonization and disease in exposed infants is presented in Table 89-3.

Infants with localized gonococcal infection other than GON should have cultures obtained of blood, CSF (although meningitis is rare), and the site of infection, if feasible. They should be hospitalized pending the availability of culture results (see the later discussion of treatment).

Systemic Disease in the Neonate

Disseminated disease occurs in 1 percent or fewer of infants who are perinatally exposed to gonococcal infection[13] (see Table 89-3). Septic arthritis is the most common form of disseminated gonococcal infection in neonates. Gonococcal arthritis of the newborn was described extensively between 1900 and 1930 by Coperman[89,90] and Wehrbein,[350] and recent case reports suggest that the disease remains similar. Clinical findings usually become evident when the infant is 1 to 4 weeks old. Although a few infants with gonococcal arthritis will have evidence of GON or other sites of mucosal or skin infection at the time of onset of arthritis, most do not. Concurrent gonococcal arthritis in both mother and newborn infant has been described.[150]

The signs and symptoms of gonococcal septic arthritis are similar to those of joint infection caused by other microbes in the neonatal period, including a predominance of polyarticular involvement. Infection most frequently involves the ankles, knees, wrists, and hands.[89] The hip may be infected with minimal signs other than pseudoparesis. Involvement of a joint may include suppurative arthritis, inflammatory disease of the periarticular structures, and tenosynovitis. Leukocytosis usually occurs, and most infants have a positive culture and compatible Gram stain results from the synovial fluid of the involved joint.[142]

Prompt drainage of septic hips, along with initiation of antimicrobial therapy, is necessary because of the risk for development of aseptic necrosis of the femoral head. Long-term dysfunction from gonococcal infection of other joints seldom occurs.[90,156,174,203]

Although gonococcal sepsis can develop in neonates with or without associated septic arthritis, the bacteremic phase of spread to the joints from the initial sites of infection generally is typically clinically silent. Premature infants seem to be more at risk for the development of sepsis with bacteremia than are term infants. Meningitis has been documented but is an exceedingly rare manifestation of neonatal gonococcal infection.[33,156,162]

GONOCOCCAL DISEASE BEYOND THE NEONATAL PERIOD

Lower Genital Tract Infection in Prepubertal Girls

Gonococcal vaginitis or vulvovaginitis is the most common form of gonorrhea in prepubertal girls beyond the neonatal period. In contrast to that of postpubertal females, the anestrogenic vaginal mucosa of prepubertal girls creates an alkaline environment that is colonized and infected more readily with *N. gonorrhoeae*. Infection of the endocervix, urethra, paraurethral and Bartholin's glands, and upper genital tract occurs only rarely.

Gonococcal vaginitis in prepubertal girls almost always is symptomatic, with vulvar erythema and a profuse vaginal discharge (Fig. 89-6). The girl may complain of dysuria, urinary frequency, vulvar discomfort, or pain while walking.[247,310,313] Asymptomatic cases are uncommon.

Signs and symptoms should resolve promptly within a few days after treatment is initiated, but acute manifestations may persist for several weeks if the child is not treated. The natural course of disease is for the inflammation to subside and the discharge to become scant and seropurulent. Infection may resolve spontaneously but occasionally may persist until the girl reaches puberty.

FIGURE 89-6 ■ Profuse, purulent vaginal discharge in an 18-month-old girl with gonococcal vulvovaginitis. Gonococcal infections in prepubertal children are almost always the result of sexual abuse. (See companion Expert Consult website for color version.) (From American Academy of Pediatrics 2012 Red Book Collection.)

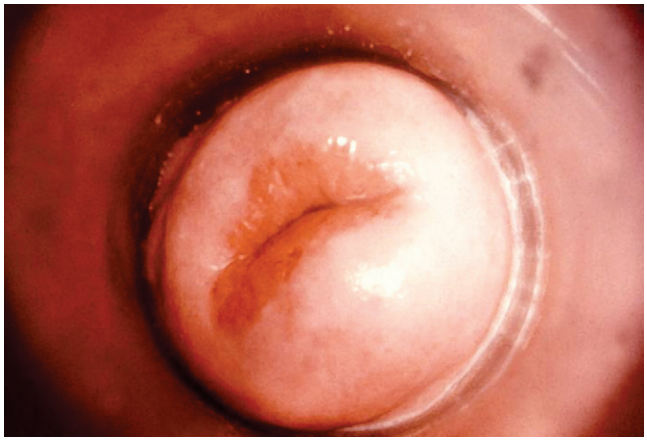

FIGURE 89-7 ■ Colposcopic view of cervix showing eroded ostium resulting from gonococcal infection. (See companion Expert Consult website for color version.) (From American Academy of Pediatrics 2012 Red Book Collection.)

Prepubertal vulvovaginitis can be caused by numerous irritative and infectious agents, including pinworms, foreign bodies, group A streptococci, *Neisseria meningitidis*, *Neisseria sicca*, and *Moraxella catarrhalis* (see also Chapter 42). Vulvovaginitis can mimic urinary tract infection, and pyuria can be seen on urinalysis with gonococcal and other causes of vulvovaginitis.[133,217]

Although ascending infection seldom occurs in this age group, it may result in salpingitis or peritonitis. One study found that 10 percent of young girls with gonorrhea had signs compatible with peritonitis, including fever, diffuse abdominal pain, leukocytosis, and decreased bowel sounds.[47] Salpingitis and periappendicitis may cause findings similar to those of appendicitis. Therefore, perineal examination for vaginal irritation or discharge should be done before performing abdominal surgery in young girls.[12]

In children with gonorrheal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is a common finding[253] because sexual abuse usually is the means of infection.

Lower Genital Tract Infection in Postmenarcheal Females

Gonococcal infections in adolescent girls are similar to those in adults. The endocervix is the primary site of urogenital infection, although the external genitalia, urethra, vulvar mucosa, and vestibular glands also may be infected. Symptoms of acute infection usually begin 3 to 5 days after exposure with the development of a profuse, purulent vaginal discharge. The vulvar tissues are inflamed, with resultant pruritus and a burning sensation. Urethritis often is present initially and can lead to dysuria with urinary frequency and urgency. Urethral discharge can be seen but is much less prominent than in males. A purulent discharge from the vestibular and paraurethral glands also may be noted.

The endocervical mucosa is edematous, inflamed, and often friable (Fig. 89-7). A profuse yellow-green discharge is present and detaches easily from the surface. The zone of endocervical ectopy that normally is present in as many as 50 percent of adolescents may appear bright red, does not bleed easily when touched with swabs, and should not be mistaken for cervicitis. Ectopy that appears swollen and friable suggests cervicitis. Nabothian inclusion cysts (transparent and grayish) also are normal findings.

Infection of the Bartholin's (major vestibular) gland or paraurethral (Skene's) gland ducts may develop during acute gonorrhea. Bartholin's gland abscesses appear as large, circumscribed painful swellings of the dorsal aspect of the labium minus (Fig. 89-8). They occur in 5 percent of females with endocervical gonorrhea.[282] Paraurethral duct abscesses appear as small painful swellings in the urethrovaginal septum and may cause dysuria. Rupture into the urethra can create a urethral diverticulum. Bartholin's gland or paraurethral duct abscesses should be incised and drained, but small asymptomatic nodules do not require drainage.

If the gonococcal infection goes untreated, the acute symptoms generally subside in 8 to 10 weeks. In a cohort of 387 adolescents 14 to 17 years of age who were evaluated by weekly quantitative cultures, 16 developed acute infection. The number of gonococci shed remained stable during the first 6 weeks of infection, although shedding patterns varied widely among the individual patients. Microbial load did not correlate with genitourinary symptoms.[332]

Persisting acute symptoms are more likely to represent reinfection than chronic infection. Chronic urethritis, thickening of the vestibular glands and paraurethral ducts, and chronic cervicitis can occur. A secondary nonspecific vaginitis can develop as a result of irritation of the mucosa from persisting profuse endocervical discharge.

Mucopurulent cervicitis can be caused by *N. gonorrhoeae*, *C. trachomatis*, *Gardnerella vaginalis*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and group B streptococci.

FIGURE 89-8 ■ Acute Bartholin's duct abscess.

The overlap in clinical manifestations of infections caused by these microbes and the frequency of infection by two or more simultaneously preclude establishing the diagnosis by clinical findings alone.

Adolescents may be unaware of their infection, especially if they have a preexisting profuse discharge as a result of nonspecific vaginitis or trichomoniasis. Early recognition and treatment of lower genital tract gonococcal infection may prevent extension to and complications of upper genital tract infection. Therefore, sexually active adolescent females should be examined for gonococcal infection as part of their routine health care.[166,299]

A review of reported complications in 1232 cases of gonococcal vaginitis in the pre-antibiotic era revealed that 35 percent had urethritis, 19 percent had proctitis, and 6 percent had peritonitis.[21]

Urinalysis may provide clues to gonococcal infection in some cases. In a cross-sectional study of 296 sexually active females 14 to 22 years of age, gonorrhea or trichomoniasis was present in 65 percent who had sterile pyuria.[178]

Upper Genital Tract Infection in Postmenarcheal Females

PID will develop in 10 to 17 percent of females with endocervical gonococcal infection. Conditions encompassed by the term *pelvic inflammatory disease* include endometritis, parametritis, salpingitis, oophoritis, tubo-ovarian abscess, and pelvic peritonitis. PID can be caused by a variety of bacteria. Anaerobes, including *Bacteroides*, *Peptococcus*, and *Peptostreptococcus* spp., are the organisms usually recovered. *N. gonorrhoeae* is present in 25 to 50 percent of cases, similar to the proportion of cases from which *C. trachomatis* is recovered. Coliform organisms, *G. vaginalis*, *M. hominis*, *U. urealyticum*, and various streptococcal species also may be involved. PID develops when these organisms are able to ascend into the uterus, fallopian tubes, and beyond from the lower genital tract. Multiple species may be involved in a single episode. Gonococcal PID often occurs during or just after menses.[30,124,171] Identification of the specific microbial cause or causes of PID is complicated by the difficulty of obtaining fallopian tube specimens before initiating therapy.

Common findings in PID include an acute onset of lower abdominal pain with tenderness, fever, tenderness on lateral motion of the cervix, adnexal tenderness that generally is bilateral, and adnexal fullness. Vaginal discharge, urinary symptoms, and irregular vaginal bleeding also may be present. In moderate to severe cases, abdominal pain frequently is bilateral, exacerbated with movement, and continuous. Nausea, vomiting, marked abdominal tenderness, an abdomen that appears tense, and fever exceeding 39°C (102.2°F) may be present. Such patients often appear to be ill and may have tachycardia consistent with the height of fever.[307] Leukocytosis and elevated erythrocyte sedimentation rates are common findings. Alternatively, PID may be clinically silent or cause only mild pain without discernible tenderness, vaginal discharge, or leukocytosis. Such mild cases can go unrecognized by patients and physicians.

Establishing the diagnosis of PID may be difficult, and the differential diagnosis includes numerous other lower abdominal conditions, such as appendicitis, ectopic pregnancy, cholecystitis, mesenteric adenitis, pyelonephritis, and septic abortion. Sonography and pregnancy testing may be helpful in diagnostic decision making. No single symptom, sign, or laboratory finding is sensitive and specific for the diagnosis of PID. Combinations of findings can improve the sensitivity but do so at the expense of reduced specificity, and vice versa.

Initiation of empirical therapy for PID should be considered if the minimal criteria of lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness all are present and no other cause for these findings is readily apparent. More elaborate evaluation may be needed in some cases because incorrect diagnosis and management might lead to unnecessary morbidity. Additional criteria that support the diagnosis of PID include an oral temperature higher than 38.3°C (101°F), an abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, increased C-reactive protein level, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*. Some cases may require pursuit of definitive criteria for diagnosing PID, which include histopathologic evidence of endometritis on endometrial biopsy, transvaginal or abdominal ultrasonography or other imaging studies that show thickened fluid-filled fallopian tubes with or without free pelvic fluid or a tubo-ovarian abscess, and laparoscopic abnormalities consistent with PID.[60,186]

The outcome for fertility probably is improved with prompt and vigorous therapy. In the past, physicians recommended that all adolescents thought to have PID be hospitalized for therapy. More recently, inpatient observation and treatment have been recommended when a surgical emergency (e.g., ectopic pregnancy or appendicitis) cannot be excluded; when compliance with or tolerance of an outpatient treatment regimen and follow-up within 72 hours cannot be ensured; when the illness appears to be severe (e.g., pelvic or tubo-ovarian abscess, overt peritonitis); or when the patient is immunocompromised, is pregnant, or has failed to respond to outpatient therapy.[5] All courses of therapy should include treatment that is appropriate for *C. trachomatis* and other causes of PID, in addition to *N. gonorrhoeae*.

Complications of PID include tubo-ovarian abscess, perihepatitis (Fitz-Hugh-Curtis syndrome), future ectopic pregnancy, and infertility. Perihepatitis is characterized by right upper quadrant abdominal pain that may radiate to the shoulder. Nausea, fever, and other signs and symptoms of PID may be present as well. Leukocytosis occurs commonly, and liver enzymes are elevated in some cases. The differential diagnosis of perihepatitis includes pleuritis, cholelithiasis, subphrenic abscess, and perforated ulcers.[216]

An estimated 15 percent of women may become sterile after a single episode of PID and 50 percent after three infections. Because of scarring and fibrosis in the fallopian tube, patency is compromised and fertility is jeopardized.[53,124,125] PID in adolescents is particularly likely to result in infertility and ectopic pregnancy (Fig. 89-9), and PID is the single most common cause of infertility in young women.[44,243] Between 1970 and 1980, the rate of ectopic pregnancies per 1000 live births increased from 4.8 to 14.5, and between 1975 and 1981, the rate of hospitalization of females 15 to 19 years of age for salpingitis was 4/100,000.[348] These increases correlated with rising rates of gonococcal infection in the affected populations. Data from several studies of gonococcal disease in adolescents are presented in Table 89-4.

Risk factors for the development of PID include young age at the time of acquisition of gonococcal disease or other STIs, a history of previous PID, multiple sexual partners, and the use of an intrauterine device (IUD) for contraception. The immature cervix may be at particular risk for progression to upper tract disease.[315] Disseminated gonococcal infection may accompany asymptomatic infection of an IUD,[85] and the rate of acute PID in those who use IUDs may be increased.

Genital Tract Infection in Males

Gonococcal urethritis in prepubertal boys is a less frequent event than vaginitis in girls because of gender differences in rates of sexual abuse. In children with gonorrheal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is a frequent finding.[253]

Urethritis is the primary manifestation of gonococcal infection in males of all ages beyond the neonatal period (Fig. 89-10). Even in young boys, the disease usually is symptomatic and resembles gonococcal urethritis in men.[96,136] Dysuria, purulent discharge, or both develop 2 to 7 days after exposure. Patients generally are afebrile. Purulence typically is greater than with nongonococcal urethritis, but symptoms often are mild enough that patients (or their parents) may delay seeking medical care for weeks. Associated inguinal adenopathy occurs rarely.

FIGURE 89-10 ■ Purulent male urethral discharge resulting from gonorrhea with an associated pyodermal lesion on the glans. (See companion Expert Consult website for color version.) (From American Academy of Pediatrics 2012 Red Book Collection; originally from Centers for Disease Control and Prevention.)

At least 5 percent of cases of gonococcal urethritis in males are asymptomatic, and asymptomatic infection can occur at all ages. Asymptomatic pyuria is a manifestation with which the pediatrician should be familiar.[103] It may be the only finding in some cases and should raise suspicion of gonococcal or chlamydial infection in boys who may have been sexually abused or in sexually active adolescent males.

Males with asymptomatic infection are a major reservoir for transmission to their sexual partners.[101] Untreated male urethral infection may persist for as long as 6 months.

Complications of gonococcal infection in males now occur much less frequently than in the pre-antibiotic era. Epididymitis is the most common complication. Unilateral swelling, pain, and erythema in the posterior aspect of the scrotum are the usual features. Fever may occur. If untreated, the infection may progress to involve the ipsilateral testis. Hydrocele may result from secretion of fluid into the potential space of the tunica vaginalis. Epididymitis can lead to testicular infarction, abscess, infertility, prostatitis, paraurethral abscesses, and penile lymphangitis, but these local complications are rare findings. Perihepatitis in males has been described but occurs extremely infrequently.[205]

Disseminated Disease

Dissemination requires invasion of the bloodstream from local infection of the mucous membranes of the genital tract, rectum, pharynx, or conjunctiva. Bacteremia then can lead to infection of other sites. The risk for dissemination in children after mucosal infection appears to be higher than the 1 to 3 percent rate in adults. Dissemination in adults seems to be more common with asymptomatic infections, many of which are caused by AHU^- gonococcal strains (see earlier discussion of pathogenesis).[200] Deficits in the complement system have been associated with disseminated disease in adults, but the frequency of such deficiencies in children is unknown.

As in neonates, gonococcal arthritis is the most common form of disseminated disease in older children, adolescents, and adults. The ankles, knees, wrists, and hands are involved most frequently. The clinical findings are not distinct from those of other microbial causes of septic arthritis. Polyarticular involvement occurs less frequently than in neonates.[94] Gram stain and synovial fluid cultures often are negative. Therefore, empirical coverage for *N. gonorrhoeae* must be considered when septic arthritis develops in a sexually active adolescent or a child who may have been sexually abused.

Typically, the patient has a single most severely affected joint, and associated myositis and tenosynovitis may be prominent findings. Gonococcal arthritis in older children and adolescents resembles that in adults and may be accompanied by cutaneous lesions (Fig. 89-11).[4] Osteomyelitis rarely occurs but has been reported in all age groups, usually in association with septic arthritis.[9]

Treatment of gonococcal arthritis depends on prompt recognition of the disease. Cultures of all mucous membranes (i.e., nasopharyngeal, rectal, vaginal or endocervical, and conjunctival), blood culture, and aspiration of the involved joint should be performed. The local signs of gonococcal arthritis may not respond to antibiotic therapy for several days. Serial needle aspiration rather than open drainage usually is sufficient for relief of pain and recovery without sequelae (the hip may be an exception).

Gonococcemia is clinically silent generally but can cause a syndrome of migratory polyarthralgia, fever, and rash that precedes the onset of arthritis by several days to a week. The symptomatic course normally is only mild to moderate in severity. Blood cultures often are negative by the time care is sought. Gonococcemia-related symptoms may resolve after several days, even without treatment. Rare cases can resemble meningococcemia with purpura and fulminant sepsis with disseminated intravascular coagulopathy. These cases sometimes can be fatal.[266]

The skin lesions associated with gonococcemia usually are pustules on an erythematous base (see Fig. 89-11), but petechiae, papules, and hemorrhagic bullae can develop. The development of skin lesions in conjunction with septic arthritis also has been referred to as the arthritis-dermatitis syndrome. The lesions usually arise on the extremities and are fewer than 20 in number. Low-grade fever is most common, but high fever with shaking chills may occur. Tenosynovitis is present in a fourth of these patients. Leukocytosis, pyuria, and elevated liver enzyme test results may be seen. The resultant septic joints generally become clinically apparent during the second week after the onset of disseminated infection.

Anorectal Gonorrhea

Gonococcal anorectal infection (proctitis) frequently is asymptomatic but can be associated with pruritus, tenesmus, purulent discharge, or rectal bleeding. Rectal infection can occur as a result of rectal intercourse or inoculation from vaginal secretions. Approximately 40 percent of females with genital gonococcal infection have positive anorectal cultures. Rectal infection is an unusual finding in males who have not engaged in rectal intercourse.[325]

FIGURE 89-11 ■ Skin lesion typical of the arthritis-dermatitis syndrome of disseminated gonococcal infection: necrotic pustule with an erythematous halo overlying proximal phalanx of index finger. (Courtesy Daniel P. Krowchuk, MD.)

Pharyngeal Gonorrhea

Pharyngeal gonococcal infection in all age groups beyond the neonatal period is acquired by orogenital contact. Pharyngeal gonorrhea may be asymptomatic, without evidence of inflammation, or may cause an exudative tonsillopharyngitis that can mimic group A streptococcal or viral infection. Cervical adenopathy may be present in some cases. In sexually abused children, the pharynx may be the only site of infection. It may be the sole culture-positive site in some cases of disseminated gonococcal infection, and pharyngeal infection possibly is a factor predisposing to dissemination. Pharyngeal infection usually resolves spontaneously within 10 to 12 weeks but should be treated when recognized.* In a recent study of 14- to 21-year-old females hospitalized in a children's hospital or seeking care in a public health clinic, pharyngeal gonorrhea prevalence among adolescents was 3.5 percent and 6.8 percent, respectively.[138]

Conjunctivitis Beyond Infancy

Gonococcal ophthalmia occasionally is seen in children and adults. Direct inoculation of the eye can occur as a result of transmission of fomites from infected persons. Clinical findings typically include a profuse purulent discharge, chemosis, eyelid edema, keratitis, and fever. The initial ocular discharge may be watery before turning purulent. The acute phase may mimic orbital cellulitis. Untreated infection, as with neonates, can lead to corneal opacification, ulceration, and rupture of the globe with resultant visual loss. Some cases may be minimally symptomatic, with a low-grade inflammatory response followed by spontaneous resolution.[213,217,273]

*References 1, 42, 73, 95, 154, 253, 263, 314, 353, 357.

Other Forms of Gonococcal Disease

Gonococcal meningitis is a rare condition that may occur with or without associated signs of gonococcemia or septic arthritis. Pyomyositis of the biceps and soft tissue abscesses remote from the genital area have been reported. A gonococcal abscess arising in an area of blunt trauma to a hand has been described in an adolescent with associated endocervical infection.[144] An abdominal wall abscess resulting from *N. gonorrhoeae* infection in a 22-month-old male child without other foci of infection has been described.[115] Ventriculoperitoneal shunt–associated infection, endocarditis, and myocarditis caused by *N. gonorrhoeae* have been reported in adults and can be expected to occur occasionally in children and adolescents.[171] These manifestations of gonococcal infection seldom are seen in children.

DIAGNOSTIC TESTING

Isolation of *N. gonorrhoeae* in culture remains the standard for diagnosing gonococcal infection, but nonculture, DNA-based tests have become widely used in recent years. Uses of these tests are listed in Table 89-5. Only culture should be used for rectal or pharyngeal specimens. Serologic tests based on complement fixation, latex agglutination, enzyme-linked immunosorbent assays, and other techniques have been developed, but the sensitivity of these methods is only about 70 percent, which limits their use primarily to studies of immune response and pathogenesis.[173,175,300]

The Centers for Disease Control and Prevention (CDC) also has defined three levels of diagnosis based on clinical and laboratory findings. They are more stringent than the case definitions used for public health surveillance. A *suggestive diagnosis* is defined by presence of

TABLE 89-5 **Laboratory Testing of Specimens for the Presence of *Neisseria Gonorrhoeae***

Clinical Indication for Testing	Testing Method and Specimen Type
Suspected female genitourinary tract infection	1. Culture performed on an endocervical swab specimen (adolescents or adults) or vaginal swab specimen from prepubescent females* 2. NAAT (transcription-mediated amplification tests preferred) performed on vaginal specimens or urine (may be acceptable for prepubescent children undergoing evaluation for sexual abuse; see text)
Suspected male urethral infection	1. Culture performed on an intraurethral swab specimen if collecting such a specimen is acceptable and transport and storage conditions are suitable for culture†,‡ (remains medicolegal forensic standard) 2. Gram stain of urethral discharge (positive if intracellular gram-negative diplococci are seen) 3. NAAT or NAHT performed on an intraurethral swab specimen if collecting such a specimen is acceptable 4. NAAT performed on urine
Suspected male or female rectal or pharyngeal infection	1. Culture performed on rectal or pharyngeal swab specimens* 2. NAAT preferred if off-label regulatory requirements have been met by an available clinical laboratory
Suspected gonococcal ophthalmia (neonatal or childhood) or disseminated infection	1. Culture performed on conjunctival exudate specimens, blood, synovial fluid, cerebrospinal fluid, or pustular skin lesions with the use of nonselective media (e.g., chocolate agar) 2. Gram stain on exudates or fluid samples (synovial, cerebrospinal fluid) can be useful as an initial point-of-care test that can help guide early treatment considerations pending culture results. Should be accompanied by culture 3. Some NAATs may be used for conjunctival specimens
Scenario for Confirmatory Testing	**Recommendations and Comments**
Presumptively positive culture (identification in the laboratory of typical gram-negative, oxidase-positive diplococci consistent with *N. gonorrhoeae*)	1. Preferred methods for confirmation of *N. gonorrhoeae* are (1) acid production from carbohydrates§ or (2) positive NAHT results (use of molecular method to confirm culture results) 2. Requiring both methods to be positive ensures high specificity 3. If an isolate cannot be conclusively identified as *N. gonorrhoeae* at a local laboratory, it should be sent to a reference laboratory for confirmation (especially in cases of alleged sexual abuse, sexual assault, or rape)
Positive nonculture test (e.g., NAAT, NAHT)	1. Culture with confirmation as above is the preferred additional test after a positive nonculture test if specimen transport and storage conditions are suitable. Confirmatory testing is not routinely required unless medicolegal issues exist or there is need for antibiotic susceptibility testing 2. Competitive probe format after a positive NAHT (probe) test, but this approach theoretically is less likely to detect a false-positive result 3. A different NAAT as an additional test after NAAT or NAHT has received limited evaluation; certain NAATs sometimes cross react with nongonococcal *Neisseria* spp. 4. Antibody tests that detect gonococcal antigens are not recommended for detection of *N. gonorrhoeae*

Compiled from Centers for Disease Control and Prevention: Screening tests to detect *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections: 2002. *MMWR Recomm Rep* 2002;**51**(RR-15):1-38; and Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2010. *MMWR Recomm Rep* 2010;**59**(RR-12):1-109.

*A selective medium (e.g., modified Thayer-Martin) should be used for culture of specimens from these sites.

†Transport cultures with an enriched CO_2 atmosphere can be used in some situations.

‡Selective or nonselective media may be used.

§*N. gonorrhoeae* produces acid reactions with glucose but not maltose, lactose, sucrose, or fructose. The species also does not reduce nitrates or hydrolyze tributyrin.

NAAT, Nucleic acid amplification test; *NAHT,* nucleic acid hybridization test.

mucopurulent endocervical or urethral exudate and sexual exposure to a person with gonococcal infection. A *presumptive diagnosis* requires two of three criteria: (1) typical gram-negative *intracellular* diplococci on Gram stain of urethral exudate from males or endocervical secretions; (2) growth of apparent *N. gonorrhoeae* from such specimens on culture medium, defined as typical colonial morphology, positive oxidase reaction, and typical gram-negative morphology; and (3) detection of *N. gonorrhoeae* by a nonculture laboratory test. A *definitive diagnosis* requires (1) isolation of *N. gonorrhoeae* from clinical specimens by culture, as in the second criterion for a presumptive diagnosis, and (2) confirmation of identity by biochemical, enzymatic, serologic, or nucleic acid testing (see Table 89-5).[71]

A diagnosis of *N. gonorrhoeae* infection at any site should prompt evaluation for the presence of other common STIs, if not already done (see also Chapter 42).[292]

Culture

In adults, culture of clinical specimens is 80 to 95 percent sensitive when promptly inoculated and incubated. Cultures of adult male urethral specimens, blood, and other normally sterile body sites tend to have sensitivities in the

higher range.[175] Because false-positive cultures (with appropriate laboratory confirmation; see later discussion) are not thought to occur, specificity and positive predictive values are 100 percent. Culture in adolescents and children probably has sensitivity similar to that of adults. Vaginal specimens are adequate for diagnosis in prepubertal girls, for whom obtaining endocervical specimens is unnecessary.

The use of selective media such as modified Thayer-Martin (which contains nystatin, vancomycin, trimethoprim, and colistin) is required for culture of endocervical, rectal, and pharyngeal specimens to suppress contaminating flora. Selective or nonselective media (chocolate agar) can be used with equal sensitivity for male urethral cultures. Plating of specimens on both types of media may improve the sensitivity, but the incremental yield is small and probably not cost-effective for routine practice.[31,100,283]

Gonococcal colonies become evident on agar plates within 24 to 48 hours after inoculation. Isolates are considered presumptively positive if Gram stain shows gram-negative diplococci and colonies are oxidase-positive. Further testing that demonstrates the gonococcal phenotypic pattern of acid production from selected carbohydrates or a positive result by a nucleic acid method, or both (see later discussion) is required for confirmation as *N. gonorrhoeae* (see Table 89-5).[64]

Gonococci do not tolerate drying, so clinical specimens must be plated onto appropriate media as soon as possible. Transport bottles containing medium and a carbon dioxide–enriched atmosphere should be used if definitive specimen processing will be delayed. Transport bottles should be maintained upright during inoculation to preserve the carbon dioxide atmosphere.

In sexually active females with endocervical gonococcal infection, the urethra, Bartholin's gland ducts, and Skene's gland ducts usually are infected also. Cultures of these sites may improve the overall yield or sensitivity, in part by avoiding the sampling errors that can occur with any single culture. However, the incremental yield is small enough to render obtaining such cultures unnecessary in routine clinical settings. Culture of the rectum and pharynx in females can be considered optional except when evaluating for sexual abuse.[31,192] However, in a recent study, addition of pharyngeal culture allowed detection of an additional 11 to 26 percent of cases versus cervical culture alone among 14- to 21-year-old females.[138]

In sexually active males, sites to be cultured depend on the sexual practices and the anatomic sites exposed. Among MSM, rectal and pharyngeal infections occur with frequencies similar to that of gonococcal urethritis.[37,175,229,239]

Gram-Stained Smears

In symptomatic males, a Gram stain of a urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative diplococci can be considered diagnostic of infection with *N. gonorrhoeae* (Fig. 89-12). Gram stain in this population has greater than 99 percent specificity and greater than 95 percent sensitivity.[65] Negative Gram stain results are not sufficient to exclude the diagnosis of gonorrhea. Although nonpathogenic *Neisseria* spp. and *N. meningitidis* are morphologically indistinguishable from gonococci, the former rarely are cell-associated.

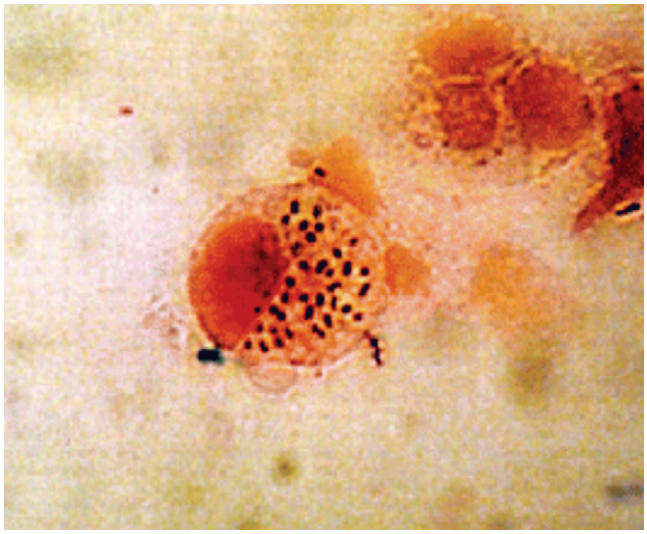

FIGURE 89-12 ■ Gram stain of gonorrheal exudate showing multiple intracellular diplococci. In male urethral specimens, this is considered diagnostic of gonococcal infection. In children and adolescent females, confirmation by culture or nucleic acid–based tests is needed (see text). (See companion Expert Consult website for color version.) (From American Academy of Pediatrics 2012 Red Book Collection.)

Gram stains of endocervical, pharyngeal, and rectal specimens are not recommended because of lower sensitivity in detection of infection at these sites. The specificity of a negative Gram stain appears to be at least 95 percent for specimens from the endocervix and rectum.[71,175,295]

Gram stains of eye exudates, joint fluid, and pustular fluid should be performed because the presence of gram-negative diplococci may help guide initial therapeutic interventions pending culture results.

Nonculture Diagnostics

Nonculture diagnostic tests have become widely used in the United States for establishing a rapid diagnosis of gonococcal (and chlamydial) infection. Many offer the advantage of using urine samples rather than the more invasive swabs and also allow *C. trachomatis* to be evaluated with the same specimen. Numerous gonococcal antigen-detection tests have been developed, but they have been supplanted largely by nucleic acid detection methods.

Nucleic acid hybridization tests (NAHTs) and nucleic acid amplification tests (NAATs) have been the nonculture tests used most commonly in the United States in recent years. NAHTs are based on a single-stranded DNA probe complementary to gonococcal ribosomal RNA (rRNA). Sensitivities are about 95 percent (less than culture), with a specificity of 99 percent.[160,175,214,265] Nucleic acid amplification tests (NAATs) use standard PCR-based assays, transcription-mediated amplification, or strand-displacement assays (SDA). These are more

sensitive than culture (see Table 89-5). False-positive reactions with PCR- or SDA-based NAATs can occur as a result of the carry-over contamination that occurs during processing or because of occasional cross reactions with commensal *Neisseria* spp. that may be present in some clinical specimens. Specificities are generally greater than 98 percent. False-negative results can occur as a result of target sequence differences (or absence) in some gonococcal clones. NAATs can be used to evaluate first-void urine specimens, which permits screening for gonococcal infection in males and females when genital examination is impractical.[80,319,344,345,354]

NAATs and DNA probe tests can detect the presence of nonviable gonococcal microbes, thereby possibly reducing the need for the stringent transport conditions often required for culture. Currently available NAATs are multiplex tests that also can detect *C. trachomatis*. NAATs are approved by the U.S. Food and Drug Administration for use with endocervical, vaginal, and urethral (male only) swab specimens and with urine specimens. They are not approved for rectal or pharyngeal specimens but are preferred for tests of these sites when clinical laboratories have met regulatory requirements for off-label procedures.[71] Some NAATs also can be used for conjunctival specimens.[5]

NAATs and DNA probe tests are adequate for rapid screening in clinical settings, and their results are adequate for making treatment decisions and public health case identifications. Culture remains the definitive test for medicolegal purposes (see the next section), although use of NAATs with confirmatory testing with a second NAAT based on an alternative DNA target is acceptable for forensic use on urine samples from girls but not boys.[27,71] In addition, because of ever-increasing resistance to the available antimicrobial agents, monitoring of gonococcal susceptibility by culture is necessary at the local level, at the very least in patients who do not respond to apparently adequate therapy.[64,354]

Medicolegal Issues Related to Diagnostic Tests

N. meningitidis and other members of the Neisseriaceae family are morphologically and often biochemically similar to *N. gonorrhoeae* and may be isolated from sites such as the vagina, blood, and nasopharynx.[111,116,355] Accurate identification of *Neisseria* organisms from any pediatric specimen is essential because misidentification of nongonococcal species as *N. gonorrhoeae* may lead to very serious social consequences for children and their families by precipitating concern regarding sexual abuse. A recent report of two cases of meningitis in young children initially misidentified as having *N. gonorrhoeae* but subsequently confirmed as having *N. meningitidis* illustrates that this is an ongoing issue.[327] Nonculture methods consistently identify more clinical specimens as positive than do standard cultures.[345] Determining whether such results indicate greater sensitivity, increased false positivity, or a combination of both has been difficult.

Because of this potential for obtaining false-positive results with nonculture NAAT or DNA probe tests, culture has been considered the medicolegal standard for children who require evaluation for suspected sexual victimization, including prepubertal girls with obvious vaginal discharge. Sequential testing using nonculture tests followed by culture if the former is positive has been proposed as a more sensitive approach than culture alone.[264] A recent multicenter study using NAATs on urine specimens, using a second NAAT based on an alternative DNA target or species-specific *N. gonorrhoeae* PCR to confirm positive results, found no false-positive results.[27] The NAAT-based approach increased the number of confirmed gonococcal infections among 485 girls who were suspected victims of sexual assault from 12, based on culture alone, to 16. This approach is now considered an alternative to culture on vaginal and urine specimens in girls. Culture remains preferred for urethral or urine specimens from boys and for pharyngeal and rectal specimens from all children.[71]

Proper Collection of Clinical Specimens

Urethral exudate from males may be obtained by passing small swabs or bacteriologic loops 2 to 4 cm into the urethra.[163] Endocervical specimens from postpubertal females are obtained by speculum examination with swabs inserted 1 to 2 cm into the external os after the cervix has been cleansed of external exudate and vaginal secretions.[291] The swab should be rotated one full revolution and withdrawn. Self-obtained vaginal swabs also provide adequate specimens for nonculture methods.[318] This technique has been studied in adolescents. Vaginal specimens collected with tampons also can be used with nonculture methods.[337]

In prepubertal girls, cultures can be obtained from the vaginal introitus by gently swabbing the hymenal opening. Deeper insertion is not necessary. Swabs of exudates emanating from the urethral meatus or vaginal orifice also are sufficient for culture.

In persons with symptomatic anorectal infection, rectal specimens should be obtained by anoscopic means, which increases the sensitivity. In asymptomatic persons, rectal specimens can be procured by blindly inserting a swab 2 to 3 cm into the anal canal and applying lateral pressure to avoid entering any fecal mass. Swabs that are grossly contaminated with fecal matter should be discarded.[104,358]

When urine specimens can be used for nonculture methods, the first 15 to 30 mL of voided urine should be collected.[223,248] Collection of urine should be delayed at least 1 hour after the most recent void to maximize sensitivity. The posterior pharynx, tonsillar areas, and faucial pillars should be swabbed to obtain adequate specimens for the diagnosis of pharyngeal infection.[175]

ANTIMICROBIAL RESISTANCE AMONG GONOCOCCI

Gonococcal strains have been able to acquire resistance to antibiotics since the first agents were introduced. In 1986, the CDC initiated the Gonococcal Isolate Surveillance Program (GISP) to monitor the antimicrobial sensitivities of *N. gonorrhoeae* in STI clinics in 21 cities in the

United States.[58] This system consisted of 29 sites in 2010.[70]

Sulfanilamide became available in 1936 and represented a major improvement over previous therapies that included local genital irrigation with solutions of silver nitrate or potassium permanganate.[268] Widespread resistance to sulfanilamide occurred by 1944. As successive agents have become available, multidrug-resistant strains are being seen with increasing frequency in many parts of the world. Ongoing analysis of gonococcal isolates for antibiotic susceptibility to the available antimicrobial agents remains essential for maintaining effective empirical therapeutic regimens.

In the 1940s, virtually all gonococcal isolates were highly susceptible to penicillin. Despite a gradual increase in the mean minimal inhibitory concentration (MIC) to penicillin from the mid-1950s through the mid-1970s, almost all strains had penicillin MICs of less than 0.5 μg/mL. This low-level resistance is mediated by alterations at a genetic locus called *penA* that result in modification of its product, penicillin-binding protein 2. Two other loci designated *mtr*, which encode an efflux pump that reduces concentrations of multiple antibiotics, and *penB*, which is an allele of *por*, the gene of the porin protein, also mediate low-level resistance to penicillins. *penB* encodes a porin with a mutation that decreases permeability to hydrophilic antibiotics.[140]

In 1976, strains of *N. gonorrhoeae* were discovered that had acquired plasmid-conferring resistance to penicillin through the production of penicillinase (a TEM-1 β-lactamase). These strains were found in many parts of the Far East and in London, and in the former they constituted approximately 30 percent of the isolates in some cities. The strains caused the expected spectrum of clinical disease, and treatment with penicillin was not effective. Penicillinase-producing gonococci contain one of two closely related 5.3- or 7.2-kb plasmids (Pc^r) that carry a Tn2 transposon system. This plasmid appears to have been acquired from *Haemophilus ducreyi*.[8,49,78,270] In 1983, an outbreak of chromosomally mediated, penicillin-resistant (MICs of 2 to 4 μg/mL), non–penicillinase-producing gonococci was reported from North Carolina.[129] Such strains were seen subsequently in other areas of the country.

Resistance to tetracycline antibiotics emerged in the 1980s and subsequently increased. Three chromosomal loci designated *mtr*, *penB*, and *tet* mediate low-level resistance. High-level resistance to tetracycline is conferred by *tetM*, which resides on a 38-kb plasmid (Tc^r) that is a derivative of the 36-kb conjugal plasmid. *tetM* produces a cytoplasmic protein that protects ribosomes from tetracycline. Tc^r gonococci can transfer this plasmid, as well as Pc^r, efficiently to other gonococcal strains.[246,329]

Spectinomycin resistance was described first in 1987 in U.S. military personnel in Korea. This agent had been introduced as the drug of choice there in 1981 because of high rates of penicillin resistance. Treatment failures actually began to occur in 1983. Resistance is chromosomally mediated and results in alteration of the ribosomal target site of the drug.[32,49] The widespread use of spectinomycin was associated with a decline in the rate of penicillin resistance.[32] Many gonococcal strains in some parts of the world also are resistant to streptomycin.[247] All gonococcal strains tested in the United States in recent years have been susceptible to streptomycin.[70]

Ciprofloxacin and other fluoroquinolone antibiotics became widely available for the treatment of gonococcal infection in the 1980s. Low-level resistance to fluoroquinolones is associated with mutations in the DNA gyrase gene *gyrA*, and high-level resistance has been linked to mutations in the topoisomerase gene *parC*.[184] Resistance to these agents has been noted since the early 1990s in areas of Southeast Asia.[131] In Hawaii, in 1999, 9.5 percent of isolates were resistant to ciprofloxacin, but resistance elsewhere in the United States was low, at 0.2 percent.[62,63] In 2000, fluoroquinolones no longer were recommended for initial treatment of gonococcal infection in Asia, the Pacific Islands, or Hawaii. In 2002, nonuse was extended to the state of California, and in 2004, to MSM throughout the United States. During the first 6 months of 2006, 13.3 percent of isolates collected through GISP were resistant to ciprofloxacin (and thus all other quinolone antibiotics). Among gonococcal isolates from MSM and heterosexual males from U.S. states other than California and Hawaii, ciprofloxacin-resistant rates were 30.7 and 5.1 percent, respectively. In April 2007, the CDC no longer recommended the use of fluoroquinolones for the treatment of gonococcal infections in the United States.[68] Quinolone resistance peaked at 14.8 percent of GISP isolates in 2007 and was 12.5 percent overall in 2010. Prevalence was 23.9 percent among isolates from MSM versus 7.9 percent among men who have sex only with women.[70]

In 1989, 13 percent of the *N. gonorrhoeae* isolates evaluated were resistant to penicillin, tetracycline, or both.[59] In 1999, such strains accounted for 28 percent of all isolates.[63] Rates of resistance to these two agents have fallen slightly in the United States since that time, with 9 percent being resistant to penicillin and 17 percent resistant to tetracycline in 2005.[67] Overall in 2010, 27.2 percent of isolates evaluated by GISP were resistant to penicillin, tetracycline, ciprofloxacin, or some combination of those antibiotics.[70] Tetracycline resistance was 21.6 percent in 2011.[72]

Strains resistant to azithromycin and erythromycin have been identified in the United States.[62] The distribution of azithromycin MICs has shifted upward in the last decade, although the proportion of GISP strains with MICs of 2.0 μg/mL or higher was 0.3 percent in 2011.[67,72] One isolate with azithromycin MIC greater than 256 μg/mL was found in Hawaii in 2011.[198] Rifampin resistance is also high in some areas of the world.[257]

During the past few years there has been upward creep in cefixime MICs in the United States and other countries, along with reports of treatment failures with the recommended 400 mg oral dose of this agent.[72,224,341] MICs of 0.5 μg/mL or higher are considered to have decreased susceptibility to cefixime. Nationally in the United States, in 2011, 1.5 percent of GISP isolates had cefixime MICs of 0.25 μg/mL or higher, a threshold used by GISP for monitoring emerging resistance to cephalosporins (Fig. 89-13). In the Western United States, 3.2

percent of isolates had MICs at or above 0.25 μg/mL. These observations prompted removal of cefixime from recommended options for empirical treatment of uncomplicated gonococcal infections in the United States in August 2012. Ceftriaxone MICs have increased minimally overall to date, but isolates with MICs of 1 to 2 μg/mL have been reported.[72,341]

These events raise concerns about emergence of multidrug resistant gonococcal strains. Ongoing monitoring of antimicrobial resistance in *N. gonorrhoeae* is warranted. New antimicrobial agents will be needed.

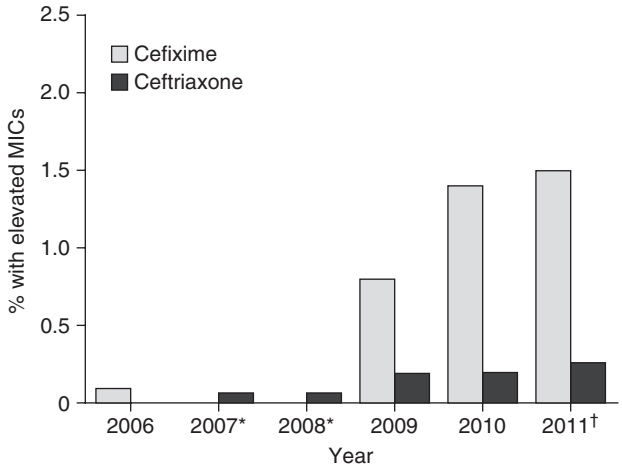

FIGURE 89-13 ■ Percentage of urethral *Neisseria gonorrhoeae* isolates (n = 32,794) with cefixime minimum inhibitory concentrations (MICs) ≥0.25 μg/mL and ceftriaxone MICs ≥0.125 μg/mL, from the Gonococcal Isolate Surveillance Project, United States, 2006 to August 2011. MICs have risen steadily during the past few years as a result of alterations in the microbial penicillin-binding proteins.
*Cefixime susceptibility was not tested during 2007 and 2008.
†Results from January through August, 2011.

TREATMENT

Because of ever-changing gonococcal susceptibility patterns and variations in susceptibility in different international regions, practitioners must remain alert for modifications of treatment guidelines for their respective geographic locations. Based on the current patterns of antimicrobial resistance in prevalent *N. gonorrhoeae* strains in the United States, the third-generation cephalosporin ceftriaxone is the only remaining antibiotic routinely recommended as initial therapy in children and adults as of August, 2012.[72]

The recommendations for treatment of childhood gonorrhea in the United States discussed in this section and listed in Tables 89-6 and 89-7 are based on 2010 guidelines from the CDC[65,68,69] and the 2012 Report of the Committee on Infectious Diseases of the American Academy of Pediatrics.[5] CDC guidelines are based on the stringent clinical efficacy criterion of an expected 95 percent efficacy with lower bound of 95 percent confidence interval of 90 percent.[254]

Treatment of Infants Born to Mothers with Gonococcal Infection

Infants born to mothers with untreated gonorrhea are at high risk for acquiring infection (e.g., GON and disseminated infection); consequently, even without overt signs of infection, such infants should be treated with a single injection of ceftriaxone (see Table 89-6). Ceftriaxone should be given cautiously to hyperbilirubinemic infants, especially premature ones. A single dose of cefotaxime 100 mg/kg intravenously or intramuscularly is an acceptable alternative. Topical prophylaxis for neonatal ophthalmia is not adequate therapy for documented infections of the eye or other sites.[71]

TABLE 89-6 **Treatment of Gonococcal Infections in the Neonatal Period**

Disease Category	Treatment Regimen	Comments
Infants born to mothers with gonococcal infection *or* Gonococcal ophthalmia neonatorum (GON) or other focal sites of infection (i.e., rectum, pharynx, vagina, urethra)	Ceftriaxone 25-50 mg/kg IV or IM, not to exceed 125 mg (single dose)*†‡	Infants with GON should receive eye irrigation with saline solution immediately on recognition and at frequent intervals subsequently until the discharge is eliminated
Disseminated gonococcal infection (septic arthritis, sepsis, meningitis) or scalp abscess	Ceftriaxone 25-50 mg/kg IV or IM once daily for 7 days (10-14 days for meningitis) *or* Cefotaxime 25 mg/kg IV or IM every 12 hours for 7 days (10-14 days for meningitis)	Cefotaxime is preferred for infants with hyperbilirubinemia who require more than a single dose of therapy If meningitis is present, higher or more frequent doses in the recommended ranges may be needed

Data compiled from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2010. *MMWR Recomm Rep* 2010;**59**(RR-12):1-109; and American Academy of Pediatrics: Gonococcal infections. In: Pickering LK, editor. *2012 red book: report of the Committee on Infectious Diseases*. 27th ed. Elk Grove Village, Ill: American Academy of Pediatrics; 2012, p. 336-344.
*If ceftriaxone is unavailable or contraindicated, cefotaxime, 100 mg/kg IV or IM (single dose) is an alternative.
†Topical agents alone are inadequate and unnecessary when recommended systemic antibiotics are given.
‡For GON, some experts prefer to continue parenteral therapy with one of these agents until blood (with or without cerebrospinal fluid) cultures have been negative for 48 to 72 hours.
IM, Intramuscularly; *IV,* intravenously.

TABLE 89-7 **Treatment of Gonococcal Infections in Children Beyond the Neonatal Period**

	Prepubertal Children Who Weigh <100 lb (45 kg)[a]	Patients ≥8 Years Old and Who Weigh >100 lb (45 kg)[a]
Uncomplicated Gonococcal Infections		
Vulvovaginitis, endocervicitis, urethritis, proctitis or pharyngitis	Ceftriaxone 125 mg IM in a single dose[b]	Ceftriaxone 250 mg IM in a single dose[b]
Conjunctivitis[c]	Ceftriaxone 50 mg/kg (maximum, 1 g) IM in a single dose	Ceftriaxone 1 g IM in a single dose
Disseminated Gonococcal Infection		
Septic arthritis, sepsis, or arthritis-dermatitis syndrome[d]	Ceftriaxone 50 mg/kg/day (maximum, 1 g/day) IV or IM once daily for 7 days[e,f]	Ceftriaxone, 1 g IV or IM once daily for 7 days[e,f]
Meningitis or endocarditis[g]	Ceftriaxone 50 mg/kg/day (maximum, 2 g/day) IV or IM given twice daily; for meningitis, the duration is 10-14 days; for endocarditis, the duration is at least 28 days	Ceftriaxone 1-2 g IV twice daily; for meningitis, the duration is 10-14 days; for endocarditis, the duration is at least 28 days
Epididymitis Pelvic inflammatory disease		Ceftriaxone, 250 mg IM in a single dose
Treatment for presumed coinfection with *C. trachomatis*	Erythromycin base or ethylsuccinate 50 mg/kg/day (maximum 2 g/day) PO in 4 divided doses for 14 days *or* Azithromycin 20 mg/kg (maximum 1 g) PO in a single dose[i]	See text for description of options Azithromycin 1 g PO in a single dose *or* Doxycycline 100 mg PO twice daily for 7 days[h]

Note: See text for discussion of alternative treatment options, including those for patients with allergies to the recommended regimens above.

Data compiled from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2010. *MMWR Recomm Rep* 2010;**59**(RR-12):1-109; American Academy of Pediatrics: Gonococcal infections. In: Pickering LK, editor. *2012 red book: report of the Committee on Infectious Diseases.* 27th ed. Elk Grove Village, Ill: American Academy of Pediatrics; 2012, p. 336-344; and Centers for Disease Control and Prevention. Update to CDC's sexually transmitted diseases guidelines, 2010: oral cephalosporins no longer a recommended treatment for gonococcal infections. *MMWR Morb Mortal Wkly Rep* 2012;**61**:590-594.

[a]If ceftriaxone is not available, alternatives are (1) in children <45 kg weight: cefixime 8 mg/kg (maximum 400 mg) PO in a single dose, plus test of cure in 1 week; and (2) in children >8 years old and >45 kg weight: cefixime 400 mg in a single oral dose plus test of cure in 1 week.

[b]Therapy for potential (presumptive) coinfection with *Chlamydia trachomatis* also is recommended.

[c]Eyes should be lavaged with saline initially and at regular intervals until secretions no longer continue to accumulate.

[d]Hospitalization should be considered for children based on clinical severity, including those (1) who are unlikely to receive the prescribed treatment because of personal or parent/guardian failure to adhere to the regimen or (2) whose infection has not responded to outpatient therapy.

[e]Some experts advise a 10- to 14-day course of therapy for gonococcal sepsis or septic arthritis.

[f]For older children and adolescents, parenteral therapy can be discontinued 24 to 48 hours after improvement occurs and the 7-day course completed with an appropriate oral antimicrobial agent, based on antimicrobial susceptibility results.

[g]Children or adolescents with gonococcal meningitis or endocarditis should be hospitalized initially.

[h]Prevalence of tetracycline resistance is high among Gonococcal Isolate Surveillance Project isolates, particularly among those with elevated minimum inhibitory concentrations to cefixime. Azithromycin thus is the preferred second antimicrobial for treatment of presumed chlamydial coinfection.

[i]Data are limited regarding efficacy of azithromycin for treatment of chlamydia in young children, but the single dose and favorable side effect profile make this agent a reasonable choice.

IM, Intramuscularly; *IV,* intravenously; *PO,* orally.

Treatment of Neonates with Gonococcal Infection

Neonates with suspected gonococcal infection of any site, including GON, should be admitted to the hospital for parenteral antibiotics and any needed supportive care. Many but not all experts recommend that CSF studies be performed even in afebrile, otherwise well-appearing infants whose only clinical manifestation is apparent GON.

The presence of typical gram-negative diplococci in Gram-stained specimens is sufficient justification to begin treatment of GON or gonococcal infection in other sites. The absence of gram-negative diplococci in Gram-stained specimens is not sufficient to abrogate presumptive treatment of GON in a neonate with conjunctival exudate.

Tests for concomitant *C. trachomatis* infection, HIV infection, and congenital syphilis should be performed in infants with gonococcal infection at any site. The mother and her partners should be evaluated for gonococcal infection (and other STIs) and treated according to the recommendations for gonococcal infection in adolescents and adults (see the next section).

Infants with GON can be treated with a single dose of ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly, not to exceed 125 mg (see Table 89-6). This regimen also may be used for infants with other sites of nondisseminated gonococcal infection, including the rectum, pharynx, vagina, and urethra. A single dose of

cefotaxime 100 mg/kg given intravenously or intramuscularly is an alternative treatment of GON. Some experts prefer to continue parenteral therapy with one of these agents until blood cultures (with or without CSF cultures) have been negative for 48 to 72 hours. Infants with GON also should receive eye irrigation with saline solution immediately on recognition and at frequent intervals until the discharge is eliminated. Topical antimicrobial agents alone are inadequate and unnecessary when the recommended systemic antibiotics are given.[5,71,133,208]

Simultaneous infection with *C. trachomatis* should be considered a potential explanation for neonates who do not respond satisfactorily to the recommended treatment.

Disseminated Gonococcal Infection or Scalp Abscess

The recommended therapy for gonococcal arthritis, scalp abscess, and sepsis is ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly given once per day for 7 days or cefotaxime 50 mg/kg/day given intravenously or intramuscularly in two divided doses for 7 days will be adequate for many infants (dose and interval adjustments may be needed depending on gestational and chronologic age and other clinical considerations). Cefotaxime is preferred for infants with hyperbilirubinemia. For gonococcal meningitis, treatment should be continued for 10 to 14 days, with consideration of the use of higher daily doses of these agents (see Table 89-6).[71]

Treatment of Gonococcal Infections Beyond the Neonatal Period

Treatment recommendations for children and adolescents with uncomplicated and complicated gonococcal infection, including PID, are outlined in Table 89-7. All treatment regimens include agents active against *C. trachomatis* in addition to *N. gonorrhoeae* (see later discussion).

Children who are postpubertal or who weigh more than 45.4 kg (100 lb) may be treated with dosage regimens as defined for adults. The recommended regimens generally have not been studied in populations of prepubertal children with either uncomplicated or complicated gonococcal infection, but these regimens are likely to be highly effective in most cases, as they are for older adolescents and adults. In adults with an uncomplicated gonococcal infection at any site, 99 percent of cases are cured by ceftriaxone. As a general rule, children treated with ceftriaxone do not require follow-up cultures, but if treatment regimens other than ceftriaxone are used, follow-up cultures may be indicated.[71]

The standard intramuscular dose for older children and adults was increased to 250 mg from 125 mg in 2010. This change was made due to increasingly widespread prevalence globally of strains with decreased susceptibility to cephalosporins in vitro, reports of treatment failures with the lower dose, and improved efficacy of the 250 mg dose in pharyngeal infections. Up-to-date information on treatment regimens for gonorrhea and other STIs can be obtained from the CDC website http://www.cdc.gov/std/treatment.

Alternatives to Ceftriaxone

Cefixime has an antimicrobial spectrum similar to that of ceftriaxone. Until recently, a single oral dose of cefixime was recommended for routine treatment of uncomplicated gonococcal infections. Increasing prevalence of gonococcal strains with decreased susceptibility to third-generation cephalosporins has led to the change in recommendations.[72] The 400-mg oral dose recommended until recently for adolescents and adults does not provide as high or as sustained a bactericidal concentration as that provided by a 125-mg parenteral doses of ceftriaxone. Cefixime remains effective for the majority of isolates that are fully susceptible to third-generation cephalosporins and can be used if susceptibility of a cultured isolate has been confirmed. The dosage in children weighing less than 45 kg is 8 mg/kg (maximum 400 mg) as a single oral dose. For children older than 8 years of age and weighing more than 45 kg, a single oral dose of 400 mg is used.

Other single-dose parenterally administered cephalosporins that are safe and likely effective against uncomplicated gonococcal infection in adolescents and adults include cefotaxime 500 mg intramuscularly, ceftizoxime 500 mg intramuscularly, and cefoxitin 2 g intramuscularly, with probenecid 1 g orally. None of these offer any advantage over recommended doses of ceftriaxone.[71]

Some evidence indicates that cefpodoxime 400 mg orally is effective for urogenital gonorrhea and cefuroxime axetil 1 g orally is effective for urogenital and rectal gonorrhea in older adolescents and adults. Neither agent is adequate for treatment of pharyngeal infection, at least as a single dose.[71] No data are available regarding use of these agents for gonococcal infections in children.

The fluoroquinolone antibiotics ciprofloxacin, ofloxacin, and levofloxacin have been used widely for treating gonococcal infection in adults. Cure rates for uncomplicated gonococcal infection with both agents exceed 98 percent in adults with susceptible isolates. These agents no longer are recommended for routine treatment of gonococcal infections in the United States and many other parts of the world because of substantial resistance rates.[68,69,72] They remain an option for adults, and potentially for children in selected circumstances, when the infecting gonococcal strain is known to be susceptible to them. These are contraindicated for women who are pregnant or nursing.

Spectinomycin would be an effective alternative in the United States, based on antimicrobial susceptibility surveillance, in most cases in which other agents cannot be used.[5] However, spectinomycin remains unavailable in the United States as of August 2012. Azithromycin (i.e., the higher, 2-g, dose in adolescents and adults) may be useful in circumstances in which patients are unable to take standard regimens because of allergies, pregnancy, or concerns of age-related toxicity (e.g., dental staining with tetracyclines) or when no other alternatives are available. Azithromycin 1 g orally as a single dose meets alternative regimen criteria, but treatment failures have been documented and there are ongoing concerns about

rapid emergence of macrolide resistance among *N. gonorrhoeae* should this regimen be used widely.[71]

Uncomplicated Pharyngeal Gonorrhea

Gonococcal infection of the pharynx is more difficult to eradicate than infection of urogenital and anorectal sites. Chlamydial infection of the pharynx is an unusual occurrence, but genital coinfection may be present. A single dose of ceftriaxone 250 mg intramuscularly is the preferred treatment of uncomplicated pharyngeal gonococcal infection. A single dose of an oral fluoroquinolone may be used if the isolate is known to be susceptible to these agents. Spectinomycin (when available) is unreliable against *N. gonorrhoeae* in the pharynx; it eradicates the organism in only approximately 50 percent of cases.[71]

Pelvic Inflammatory Disease

PID is presumed to be polymicrobial, including anaerobes, in addition to *N. gonorrhoeae*. Combination antimicrobial regimens are required. Hospitalization is warranted for adolescents who are pregnant; have potential surgical emergencies other than PID, including tubo-ovarian abscess; have not responded to an oral regimen already prescribed for the episode; are unable to follow or tolerate an oral regimen; or have severe illness, nausea and vomiting, or high fever.

Two parenteral regimens are recommended for those requiring hospitalization: (1) cefotetan 2 g intravenously every 12 hours *or* cefoxitin 2 g intravenously every 6 hours, combined with doxycycline 100 mg orally or intravenously every 12 hours; or (2) clindamycin 900 mg intravenously every 8 hours plus gentamicin, using a loading dose intravenously or intramuscularly of 2 mg/kg of body weight followed by maintenance doses of 1.5 mg/kg every 8 hours. Single daily dosing of gentamicin 3 to 5 mg/kg per dose can be used. Parenteral therapy can be discontinued 24 hours after clinical improvement. Oral doxycycline or clindamycin should then be continued to complete a total of 14 days of therapy. Clindamycin is preferred for course completion when tubo-ovarian abscess is present. An alternative regimen, based on limited data, is ampicillin-sulbactam 3 g intravenously every 6 hours plus doxycycline 100 mg orally or intravenously every 12 hours.[71]

Outpatient regimens recommended for adolescents who are not severely ill as discussed earlier and appear able to tolerate oral agents are (1) ceftriaxone 250 mg intramuscularly as a single dose plus doxycycline 100 mg orally twice daily for 14 days, with or without metronidazole 500 mg orally twice daily for 14 days; or (2) cefoxitin 2 g intramuscularly as a single dose, plus probenecid 1 g orally concurrently as a single dose, plus doxycycline 100 mg orally twice daily for 14 days, with or without metronidazole 500 mg orally twice daily for 14 days. Other parenteral third-generation cephalosporins (e.g., cefotaxime or ceftizoxime) may be substituted for ceftriaxone or cefoxitin in these regimens. Limited data suggest that amoxicillin-clavulanate plus doxycycline may be effective, although gastrointestinal symptoms may limit compliance. Ceftriaxone 250 mg intramuscularly as a single dose, plus azithromycin 1 g orally once per week for 2 weeks also may be effective. Addition of metronidazole to such alternative regimens should be considered.[71]

Quinolone-based oral regimens are no longer recommended for routine use because of prevalence of gonococcal resistance to these agents. However, if a cephalosporin-based regimen is not feasible, a fluoroquinolone plus metronidazole may be used (both for 14 days) if a culture for *N. gonorrhoeae* showing positive susceptibility to quinolones is documented. Levofloxacin 500 mg orally once daily or ofloxacin 400 mg orally once daily are the agents of choice.[71]

Substantial clinical improvement is expected within 72 hours after initiation of therapy. Those failing oral regimens should be hospitalized and switched to parenteral regimens. Diagnostic testing (i.e., imaging or laparoscopy) should be considered.

Severe Allergies to Cephalosporins

Selection of alternative antibiotic therapies for persons with a history of a reaction to a cephalosporin must be guided by the severity of the reaction and the availability of suitable alternative regimens.[64] Desensitization can be considered but often is impractical. Azithromycin is probably the best available choice at this time for persons with documented severe reactions to penicillins or cephalosporins.[71] If circumstances permit delay in treatment until antibiotic susceptibility test results can be obtained, other agents such as fluoroquinolones or doxycycline may be used if the isolate is shown to be susceptible.

Azithromycin 2 g orally is effective against uncomplicated gonococcal infection in adolescents and adults, but it is expensive and frequently associated with gastrointestinal problems. Because of these issues and concern about rapid emergence of resistance, it is not recommended for routine use.[65] A single dose of 20 mg/kg (maximum, 1 g) is recommended for the treatment of chlamydial infection in children, but no dose recommendations for azithromycin are available for the treatment of gonococcal infection in children.[5]

Patients should be observed for at least 30 minutes after the ingestion of a dose of 2 g of azithromycin to monitor tolerance of the medication.[56] An oral dose of 1 g of azithromycin cures approximately 93 percent of uncomplicated gonococcal infections in adults. Although better tolerated, this dose is not sufficiently effective for routine use.

Spectinomycin 40 mg/kg given intramuscularly, with a maximal dose of 2 g, remains effective for uncomplicated infections and, if available, would be a good choice for cephalosporin-allergic patients.

Infection with Human Immunodeficiency Virus

Children and adolescents infected with HIV who acquire a gonococcal infection should receive the same treatment as persons without HIV infection.

Concurrent Syphilis Infection

A single dose of ceftriaxone is not adequate for treating syphilis. Longer courses of therapy are required with penicillin-based regimens (see Chapter 143).

Pregnancy

Pregnant women should not be treated with quinolone or tetracycline agents. Those unable to take one of the recommended cephalosporin regimens can be treated with the 2 g dosage of azithromycin. Spectinomycin would be appropriate if available.

Presumptive Treatment of *Chlamydia Trachomatis* Coinfection

Persons with gonococcal infection, including children, are at high risk for acquiring concurrent chlamydial infection. Coinfections frequently occur and were present in 50/5877 students attending an urban U.S. high school in 1998 to 1999 who participated in a school-based screening program.[258] Among adolescents in 14 U.S. juvenile detention centers from 1997 through 2002, more than 50 percent of the teens with gonorrhea were coinfected with *C. trachomatis*.[193] In adolescents, treatment of gonococcal cervicitis with drug regimens that are effective against gonococci but not *Chlamydia* has been associated with a high incidence of residual salpingitis in females and urethritis in males because of the ongoing presence of *C. trachomatis*.[267,281,284,307]

Therefore, treatment recommendations for gonococcal infections beyond the neonatal period include agents active against both organisms (Table 89-7). Neonates with gonococcal infections also should be evaluated for *C. trachomatis* coinfection. Penicillin, amoxicillin, ceftriaxone, or spectinomycin alone will fail to eradicate *C. trachomatis*. Trimethoprim-sulfamethoxazole, tetracycline, doxycycline, azithromycin, and erythromycin are effective in vitro and in many clinical forms of chlamydial disease.

Follow-Up

The recommended ceftriaxone regimens have such high cure rates that routine testing for cure is not recommended.[57,60,65,71,81] Children or adolescents who receive treatment regimens other than ceftriaxone should have test of cure by culture or nonculture methods 1 week after treatment.[72] Those who remain in at-risk environments for reinfection or for whom adherence is uncertain also should have follow-up evaluations.[5]

Treatment failures can occur, and cultures should be repeated for antibiotic susceptibility testing when symptoms persist after treatment. This precaution may lead to recognition of an antibiotic-resistant strain that could have public health implications.

Apparent treatment failure usually is the result of reinfection. Reinfection may be associated with a higher risk for PID and other complications of gonococcal infection. Therefore, retesting in 3 months for reinfection (not test of cure) is advisable for sexually active adolescents and adults, regardless of whether patients think their sex partners have been treated.[5,65]

GONOCOCCAL INFECTION AND SEXUAL ABUSE OF CHILDREN

When gonococcal infection or any other STI is identified in a prepubertal child or in adolescents who are not sexually active within their peer groups, sexual abuse must be considered to have occurred unless proved otherwise. Nonsexual transmission never should be assumed without extensive investigation of the social setting of an infected child and even then rarely.[5,252] Isolation of *N. gonorrhoeae* in cultures from children should be reported to local public health authorities and also to child protective services to ensure that the child is not exposed to further abuse. Sexual abuse has been reported in approximately 10 percent of all self-reporting populations of girls during childhood in numerous studies, and rates in boys are about 3 percent.[14,297] Approximately 1 percent of children appear to experience serious forms of sexual abuse yearly.[6]

STIs occur in 3 to 20 percent of sexually abused children.* Gonococcal infections have been found in 5 to 7 percent of sexually abused children.[107] The absence of STDs does not rule out sexual abuse when other findings suggest that it has occurred. Table 89-8 summarizes the STD diagnoses from eight studies involving children who had been evaluated for suspected sexual abuse.

The prevalence and clinical manifestations of gonococcal infection in sexually abused children are determined by the prevalence of infection in the adults who constitute the population with whom the child resides, the age of the child, and the type and frequency of sexual contact.[264] Gonorrhea was the STI recognized most frequently in abused children when gonococcal infection was highly prevalent in the general population. As a result of improved control of gonorrhea in the 1980s, fewer pediatric cases have been recognized in the United States in recent years. Nonetheless, girls who are exposed to an infected male appear to have a high rate of acquired disease. In an outbreak in an orphanage, 53 of 95 abused girls were found to have contracted infection.[2]

Among prepubertal girls who have a vaginal discharge after being sexually abused, 9 to 24 percent have been found to have gonococcal infection.[141,181,310,313] The vast majority of cases of gonorrhea in prepubertal children are associated with vaginal discharge. A recent series documented gonococcal infection in vaginal specimens from two girls evaluated for suspected sexual abuse who did not have vaginal discharge.[141] The oropharynx also is a common site of gonococcal infection associated with sexual abuse of children. This may be the only site of infection in children forced to perform orogenital sexual acts with an infected abuser. Pharyngeal infection may be asymptomatic. Although few children who suffer sexual abuse subsequently contract an STI, the diagnosis of an STI is a very important indication that the child probably

*These children also were evaluated for human immunodeficiency virus infection, and all were found to be uninfected.
†These are the data for girls evaluated in the study. Fifty-one boys were included as well, and none had evidence of gonococcal or chlamydial infection.
‡Only 85 of the girls had wet mounts performed. The percentage positive reflects this subgroup.
ND, No data.

has been abused, and an STI may be the sole finding on physical examination.[179]

Children with suspected gonococcal infection (or suspected to have suffered sexual abuse) should undergo a thorough physical examination by someone familiar with the medicolegal and clinical aspects of sexually abused children. Genital, rectal, and pharyngeal cultures should be obtained. Vaginal cultures are satisfactory in prepubertal girls. Endocervical cultures should be obtained only after puberty. Blood culture should be performed if disseminated disease is a consideration. Other sites (e.g., conjunctivae and joint fluid) should be cultured if clinically indicated. Cultures should be handled in a manner that will ensure legal acceptance if needed (see later discussion).

Nonculture methods may be used in conjunction with routine cultures to increase sensitivity in detecting gonococcal infection. These test results, when rapidly available, may permit more rapid initiation of therapy than possible with standard culture results.[264] NAATs (see earlier discussion) may be used as an alternative to culture for forensic purposes for vaginal and urine specimens in girls, but not for these specimens from boys or extragenital specimens in boys or girls.[71]

Selective criteria based on the observations that most sexually abused children do not have gonococcal infection or other STIs and that the vast majority of prepubertal girls with gonococcal infection will have clinical signs of vulvovaginitis have been developed to determine which children undergoing evaluation for sexual abuse should be tested for the presence of gonococcal infection and other STIs.[180,247,310,312,313] These criteria are (1) the known presence of any STI in the child, a sibling, another household member, a close associate of the child, or the apparent perpetrator or (2) a history or physical findings suggesting that oral, genital, or rectal contact has occurred.[180] It is highly unlikely that a sexually abused child with gonococcal or chlamydial infection will be missed through the use of these criteria. Meanwhile, the number of potentially sexually abused children who must undergo culture is greatly decreased.[180,183] Because rectal and pharyngeal gonococcal infections in girls and boys and genital infections in boys often are asymptomatic, these selective criteria may be most relevant to vaginal cultures in girls.[59]

Children who are being evaluated for sexual abuse should be evaluated for other STIs, including chlamydial disease, syphilis, hepatitis B, and HIV infection. Girls also should be evaluated for evidence of *Trichomonas vaginalis* and bacterial vaginosis by wet mount of vaginal swabs.[5,71,157,299] (Children with confirmed gonococcal infections should be evaluated similarly.) Repeat physical examination and specimen collection may be warranted 2 weeks after initial evaluation, especially when the suspected abuse event was very recent. Repeat serologic testing for syphilis, hepatitis B, and HIV may be warranted at about 12 weeks after the most recent event. A single evaluation may be sufficient if suspected abuse occurred over an extended period and a substantial amount of time has elapsed since occurrence of the last suspected episode. This is determined on a case-by-case basis.[71]

The following are general issues for evaluation and management of children who may have been sexually abused:

1. Many institutions have a clinical service or clinician with training and skill in interviewing and examining children suspected of having experienced sexual abuse. Direct involvement by or consultation with persons with such expertise should be sought at the time of initial evaluation.[262]
2. If the child is symptomatic, all available and appropriate cultures and examinations should be completed before the child receives therapy. Because asymptomatic gonococcal infections of the oropharynx and rectum occur commonly, and vaginal infection in prepubertal girls can occur without discharge, strong consideration should be given to obtaining cultures, even in the absence of symptoms, especially for children and adolescents who meet the selective criteria described earlier.[30,128,166]
3. A chain-of-custody policy that ensures proper handling, labeling, and delivery of diagnostic samples to the appropriate laboratory is essential for test results to be used in any court procedures when issues of the child's safety are being considered.
4. If sexual abuse is confirmed or suspected by the social history, physical findings, or laboratory results, the child should not be allowed to leave the evaluation site until the child's safety has been ensured. This determination usually is made by the local department of social services and may require involvement of law enforcement agencies. Temporary hospitalization of the child may be needed to permit sufficient time for any additional investigations to be performed. Reporting of suspected and confirmed cases to the social service of the county in which the child resides is required by child abuse reporting laws.
5. Most children who have been victims of sexual abuse will not have specific physical findings. Orogenital contact is a common form of abuse, as are fondling and external genital contact. These forms of abuse may occur without physical signs of injury.
6. If the child is identified with an STI, other members of the family may be infected as well. Other female children are especially likely to be infected and should be examined.[128,136]
7. Internal pelvic examination of prepubertal children rarely is necessary unless there has been major trauma or there are concerns regarding foreign bodies. Internal examination of prepubertal girls should be performed by an experienced examiner with appropriate sedation or anesthesia.
8. Children often have compelling reasons to deny abuse and frequently do not disclose sexual abuse, even to skillful forensic interviewers.[212] Denial, therefore, is not compelling disproof of sexual abuse.
9. Sexual abuse of children can be a repeated event if the perpetrator has ongoing access to the child. If the child remains unprotected and the perpetrator has an STI, the child may be subject to recurrent episodes of that STI.[211]
10. Counseling with providers skilled in helping children who have been sexually abused should be part of long-term follow-up care. The likelihood of the child having serious emotional harm is greater when abuse has been more intrusive or violent, occurred repetitively over longer periods, or was committed by someone in a close relationship with the child.[86] Parents of victims also may need treatment and support.
11. Behavioral changes such as developmentally unusual sexual behavior or acting out can be a manifestation of child sexual abuse.[134] New onset of symptoms such as abdominal pain (which may lead to medical attention when it becomes persistent), enuresis, encopresis, sleep disturbances, and phobias can be manifestations of child sexual abuse. These issues also can arise from physical or emotional abuse or from non–abuse-related social stressors and do not indicate sexual abuse per se.[86]

PREVENTION AND CONTROL OF GONOCOCCAL INFECTIONS

All gonococcal infections must be reported to public health officials. Effort should be made to evaluate, counsel, and treat all sexual partners who were exposed to the index case within 60 days before the onset of symptoms or diagnosis in the index case. If a patient's last sexual intercourse occurred more than 60 days before the onset of symptoms, the most recent sexual partner of the patient should be evaluated and treated. Patients should be instructed to avoid engaging in sexual activity until therapy is completed and any symptoms have resolved.[69] Cases in prepubertal children must be investigated to identify the source of infection (and potential perpetrator of abuse).[5]

Condoms provide a high degree of protection against the acquisition and transmission of genital gonococcal infection.[191,342] Other barrier contraceptive measures and topical spermicidal and bactericidal agents likewise can reduce the likelihood of acquiring gonococcal (and chlamydial) infection.[15,54,226,331] Postexposure prophylactic antibiotics also reduce the risk for infection developing but are unlikely to be cost-effective.[164]

When patients, including infants with ophthalmia neonatorum,[5] with gonococcal infection are hospitalized, standard precautions are recommended.

Prevention of Neonatal Infection

Pregnant women should have an endocervical culture for *N. gonorrhoeae* as part of their initial prenatal care visit. A second culture late in the third trimester should be performed for those at high risk for exposure during pregnancy. Pregnant adolescents are at higher risk for contracting gonococcal infection than are older women. Treatment options are listed in Table 89-8. Fluoroquinolone and tetracycline antibiotics should not be used during pregnancy because of potential fetal toxicity.[5]

Infants born to mothers known to have active gonococcal infection are at risk for acquiring local and disseminated infection from colonization during birth. Such infants should be treated as listed in Table 89-7. Standard preventive measures for GON were described earlier.

Vaccine Development

Research into the development of vaccines for gonococcal infection is ongoing. Although natural infection induces antibody responses directed primarily against pili, Opa, porin protein, and LOS, these antibodies do not protect against reinfection even with the same strain. Serologic correlates of immunity remain elusive, making vaccine development more difficult. Two candidate vaccines have entered clinical trials. The first, a killed whole cell vaccine studied in the 1970s, induced antibody responses and was well tolerated but not protective. A purified pilin vaccine was studied in high-risk military personnel and also was not protective.[361]

Molecular analysis of gonococcal transferrin binding proteins may have potential as vaccine antigens because of their exposure on the microbial surface. These proteins are expressed in all strains and have highly conserved gene sequences. Natural infection, however, generates little systemic or local antibody response to transferrin binding proteins.[276] Viral replicon particles based on Venezuelan encephalitis virus that express antigenic components of transferrin binding proteins or porB have shown promise in a mouse model.[361] An oligosaccharide epitope (2C7 OS) of gonococcal LOS that is expressed on most strains and is widely conserved has been identified. A peptide that mimics the structure of 2C7 OS was able to induce antibodies in mice that possess dose-responsive, complement-dependent bactericidal activity against $2C7^{+}$ strains.[255]

As with meningococcal serogroup B strains, use of combinations of recombinant antigens, potentially delivered in different formats, may be necessary. The continued emergence of antimicrobial resistance in *N. gonorrhoeae* makes vaccine development more urgent.

SUBSECTION 3 *GRAM-POSITIVE BACILLI*

CHAPTER 90

Diphtheria

Barbara W. Stechenberg

Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae* or, less commonly, *Corynebacterium ulcerans*. *Corynebacterium pseudotuberculosis*, which primarily causes infections in sheep and goats, is not discussed here because it only rarely causes a diphtheria-like disease in humans. Infection by toxigenic strains of *C. diphtheriae* causes disease that is mediated by the production of an extracellular protein. Nontoxigenic strains also can cause disease, but it is usually less severe.

Before the discovery of antitoxin at the turn of the 20th century, the "strangling angel of children," as diphtheria once was called, was a significant cause of mortality in children and adults.[109] Apparent reference to diphtheria can be traced to the 5th century BC in the works of Hippocrates, *Epidemics III*, case 7.[79] In 1821, it was recognized as a specific entity by Brettoneau, who suggested that the disease was caused by a germ and that it could be transmitted from person to person. Brettoneau coined the origin of the modern term *diphtheria* from the Greek root *diphtheria*, which means "skin" or "hide."[50] In 1883, the causative agent was identified by Klebs in stained smears from diphtheritic membranes; in 1884, Löffler grew the organism on artificial media and showed that in guinea pigs it caused a fatal infection closely resembling human disease.

The toxin was purified in 1889 by Roux and Yersin, who found that toxin alone could cause the disease. Shortly thereafter, Behring and Kitasato discovered antitoxins when they immunized animals with toxins rather than bacteria. The use of antitoxin to treat children with diphtheria at the turn of the 20th century resulted in one of the largest decreases in mortality rates by a therapeutic intervention. In Germany alone, an estimated 45,000 lives were saved each year.[62]

ETIOLOGY

Corynebacteria (Klebs-Löffler bacilli) are irregularly staining, gram-positive, nonmotile, nonsporulating, pleomorphic bacilli.[54] The club-shaped appearance of the bacillus is not a true morphologic feature, but results from attempting to grow the bacillus on media that are nutritionally inadequate (Löffler media). The organism can be recovered most readily on media containing selective inhibitors that retard the growth of other microorganisms; a sheep blood agar–based medium containing fosfomycin (for selectivity) and Tindale medium (tellurite medium with cystine) are ideal.[43,44] *C. diphtheriae* and *C.*

ulcerans grow on supplement-free blood agar, chocolate agar, and other standard media.[43]

Colonies of *C. diphtheriae* (with the exception of the lipophilic, gray *C. intermedius*) and *C. ulcerans* appear grayish white on Löffler medium. On tellurite medium, three diphtheria colony types can be distinguished: *mitis*, *gravis*, and *intermedius*. *Mitis* colonies are smooth, black, and convex; they do not ferment starch or glycogen and are hemolytic. *Gravis* colonies are gray, radially striate, and semirough; they ferment starch and glycogen and usually are not hemolytic. *Intermedius* colonies are small and smooth and have a black center; they do not ferment starch or glycogen and are not hemolytic. *C. ulcerans* colonies resemble *gravis* on Tindale medium but differ in that they are hemolytic. Similar to *gravis*, they ferment starch and glycogen. All diphtheria biotypes and *C. ulcerans* are characterized by cystinase activity and absence of pyrazinamidase activity. *C. ulcerans* may be distinguished from *C. diphtheriae* by its urease activity and ability to liquefy gelatin. Biotype *belfanti*, which does not occur in a toxigenic form, may be distinguished from the three potentially toxigenic diphtheria biotypes by its inability to reduce nitrate on Tindale medium and from *C. ulcerans* by its lack of production of urease.[43] Ribotyping and pulsed-field gel electrophoresis, both of which involve restriction digestion of genomic bacterial DNA, followed by gel electrophoresis and Southern blotting, permit more specific typing within each diphtheria biotype and aid in the epidemiologic study of outbreaks.[41,96]

C. diphtheriae biotypes *intermedius*, *gravis*, and *mitis* and *C. ulcerans* all have been observed in a toxigenic form. *Intermedius* was the biotype isolated most commonly in the United States between 1971 and 1981. Of the strains isolated, *intermedius* was found to be toxigenic more often than *mitis* or *gravis*.[36] In the United Kingdom between 1993 and 1998, and similarly in other parts of Europe, the biovar *gravis* has represented most nontoxigenic isolates, followed by *mitis* and *belfanti*.[45] Of the four nontoxigenic isolates obtained during a surveillance study of a U.S. Northern Plains Native American Community in 1996, two were of biotype *mitis* and two were *gravis*.[59] According to a United Kingdom diphtheria reference laboratory, between 1993 and 1998, the toxigenic isolates originating from Asia, Africa, and the Middle East were reported to be of the biotype *mitis* or *gravis*, with the exception of one *intermedius* isolate.[44] Golaz and associates[59] reported similar findings when they surveyed the different biotypes in South Dakota. A significant overall increase in the proportion of nontoxigenic isolates has been observed in Europe and Australia in recent years.[58] The reason for this increase is unclear, but one hypothesis is that increased immunity to toxigenic strains secondary to immunization has altered this epidemiology.

The complete genome sequence of *C. diphtheriae* biotype *gravis* has been elucidated.[33] The genome is approximately 2.48 Mb with a G+C content of 53 percent and has approximately 2320 predicted coding sequences. Metabolic analysis of the genome has revealed that *C. diphtheriae* has a complete set of enzymes for glycolysis, gluconeogenesis, pentose-phosphate pathways, anaerobic and aerobic respiration, amino acid biosynthesis, and purine nucleotide biosynthetic pathway. Most of the enzymes for the tricarboxylic acid cycle are present, with the exception of an enzyme succinyl coenzyme A (CoA) synthetase that catalyzes the conversion of succinate to succinyl CoA. An alternative enzyme present in *C. diphtheriae* may fulfill this conversion, however. The pyrimidine pathway in *C. diphtheriae* lacks an enzyme that interferes with the production of cytidine; the pathway to the biosynthesis of thymidine is complete. The genome has revealed 13 regions that are unique to *C. diphtheriae* and may serve as pathogenicity islands.[33]

No functional or significant differences have been detected in the exotoxins elaborated by the three strains of *C. diphtheriae* or by *C. ulcerans*. Only strains that are lysogenic for β-prophage or a closely related phage carrying the gene for toxin production produce diphtheria toxin. One or more *tox* gene sequences may exist in the bacterial genome, and the most highly toxigenic strains contain three or more copies.[82] Phage multiplication is not a prerequisite for the production of toxin. The capacity to synthesize toxin depends on genetic and nutritional factors. Toxin-producing cells apparently are cells in which spontaneous induction of the prophage to the phage occurs.[53] The most important factor controlling the yield of toxin is the concentration of inorganic iron in the culture medium.[39] Growth of *C. diphtheriae* in iron-deficient media prolongs the duration of induction lysis and is associated with a high yield of toxin. High concentrations of iron inhibit the production of toxin. Production of toxin also can be increased by the use of ultraviolet radiation. Conversion to a toxigenic strain occurs in nature, as has been shown by restriction enzyme studies of carriers of toxigenic and nontoxigenic strains in Manchester, England.

The ability of a strain of *C. diphtheriae* to elaborate diphtheria toxin can be shown by using several methods. In vivo studies involving necrosis of tissue in guinea pigs has been replaced by the widely used Elek[46] or modified Elek test.[49] Enzyme immunoassay[48] and polymerase chain reaction (PCR)[95] have been used to detect toxigenicity.

Diphtheria toxin is lethal to humans in an amount of approximately 130 μg/kg body weight. Cytoplasmic internalization of 1 molecule of toxin has been shown to cause cell death.[11] Toxigenic and nontoxigenic strains of *C. diphtheriae* can cause disease, but only strains that produce toxin cause disease with symptoms of myocarditis and neuritis.

EPIDEMIOLOGY

Asymptomatic human carriers serve as the reservoir for *C. diphtheriae*. Infection by *C. diphtheriae* is acquired by contact with either a carrier or an individual with active disease. The bacteria may be transmitted via droplets during coughing, sneezing, or talking. Rarely, transmission of *C. diphtheriae* occurs from skin lesions or fomites. Some reports suggest that skin carriers of *C. diphtheriae* are more infectious than nose or throat carriers and that skin carriers may serve as potential reservoirs for the initiation of epidemic spread.[12,68] In areas in which skin infections are endemic, levels of natural immunization

may be high.[21] This phenomenon is illustrated particularly well in a survey of tetanus and diphtheria immunity in a rural Kenyan community, where age was not found to be predictive of immunity and no correlation was found between levels of antibody for tetanus and diphtheria.[77]

Person-to-person transmission of *C. ulcerans* is not known to occur, although *C. ulcerans* was isolated from the siblings of two patients reported in the United Kingdom between 1995 and 1997.[18] Cases of respiratory diphtheria caused by *C. diphtheriae* and *C. ulcerans* have been documented in association with contaminated unpasteurized milk taken from cows with infected teats.[19,60,105] *C. diphtheriae* has been isolated from horses, dogs, and other domestic animals. *C. ulcerans* has been reported to infect ground squirrels in the United States, but transmission to humans has not been reported.[67,94] *C. ulcerans* is a commensal in animals and has been isolated in a wide range of wild and domestic animals.[106]

According to World Health Organization (WHO) reports, diphtheria is distributed worldwide and remains endemic in many developing areas of the world, including Asia, Africa, South America, and the Mediterranean regions.[20] Worldwide, diphtheria epidemics have occurred in a cyclic manner since the 16th century. The most recent epidemic began in 1990 in the Russian Federation, Ukraine, and the other newly independent states of the former Soviet Union.[24,107]

In the United States, the incidence and mortality rates from diphtheria in the 1920s were 140 to 150 cases/100,000, with 13,000 to 15,000 deaths each year. The number of cases gradually declined to 15 cases/100,000 population in 1945 with the extensive use of diphtheria toxoid vaccine. From 1970 through 1979, the average number of cases of diphtheria reported annually in the United States was 196.[8] From 1980 to 2004, only 57 cases of diphtheria were reported in the United States. Approximately 75 percent of the cases were in patients older than 15 years who were unimmunized or inadequately immunized.[8] From 1980 to 1995, only 4 fatal cases involving diphtheria and unimmunized children were reported.[14,87,97] In 1996, *C. diphtheriae* was isolated from a Native American population in South Dakota.[59] Only 5 cases of diphtheria have been reported since 2000. Maintenance of immunity in adults requires a booster vaccination every 10 years. The Centers for Disease Control and Prevention estimated in the mid-1990s that fewer than 50 percent of adults in the United States had received their 10-year boosters and that 40 to 50 percent of adults were susceptible to diphtheria.[52,97] In addition, the toxoid vaccine does not provide protection against nontoxigenic strains.

The incidence peaks during the cooler autumn, winter, and spring months. Several epidemics, primarily in the southern United States, have occurred in late summer and fall and corresponded to a high prevalence of *C. diphtheriae* skin infections. Between the years 1971 and 1981, the incidence of diphtheria was highest in the western United States. A 100-fold greater incidence of diphtheria occurs in Native Americans than in the general population.[36] This difference may be attributable to socioeconomic factors more than to race.

Evidence that diphtheria is diagnosed more frequently in chronic alcoholics and the indigent than in the general population is significant. In a 1993 to 1994 outbreak in St. Petersburg, Russia, 69 percent of a total of 42 deaths occurred in individuals classified as chronic alcoholics.[99] Between 1972 and 1982, three outbreaks occurred in the indigent alcoholic population living in Seattle's Skid Road.[66] Cutaneous infections accounted for 86 percent of the 1100 total cases. The first outbreak was caused by a single toxigenic *intermedius* biotype clone, whereas the other two involved nontoxigenic *mitis* and *gravis* strains. The incidence was highest in winter and spring.

Native Americans also represent a disproportionate number of diphtheria cases, the reasons for which are unclear, but apparently infection is endemic in some closely knit communities. During 1974 and 1975, 27 percent of Native Americans in the Skid Road population were affected, compared with 5 percent of the white population. In 1996, a surveillance study was conducted in a Northern Plains Native American community after *C. diphtheriae* was isolated from the skin of a resident of the community. The woman was a chronic alcoholic admitted to the hospital for detoxification and treatment of severe necrotizing leg ulcers, from which a toxigenic *mitis* biotype was isolated. In the following 4 months, 11 positive cultures were obtained from the community, including 4 positive throat swabs from asymptomatic household contacts of the index cases. Ribotyping indicated that the isolates were related closely to each other genetically and to strains obtained from past cases from the same area; they were different from organisms obtained from other parts of the United States and from the former Soviet Union, where an ongoing epidemic was occurring at the time.[26,59]

A similar study was conducted in a Koorie (Aborigine) community in Victoria, Australia, in 1994, after three cases of nontoxigenic *C. diphtheriae* endocarditis were diagnosed in the community. After screening 359 asymptomatic (with the exception of 4 people who had chronic skin ulcers swabbed) contacts of the index cases, 12 produced positive cultures for nontoxigenic *C. diphtheriae*. Of them, 5 were of the same biovar *gravis* clone as the three index cases.[69]

A major epidemic began in 1990 in the new independent states of the former Soviet Union and spread throughout the area. Between 1990 and 1997, approximately 150,000 cases of diphtheria were reported, with approximately 4000 fatalities.[65,96] The epidemic was attributed to decreasing immunization rates and immunity in adults and children and to movement of large numbers of people during the collapse of the former Soviet Union.[24,107] Apparently, multiple foci of infection existed across the continent. Most of the epidemic isolates from Ukraine and Russia were biotype *gravis*, but further molecular characterization of the *tox* genes from these areas revealed distinct epidemic strains in each location.[70] Superimposed over the steady increase in the number of cases from 1990 through 1994, a seasonal variation typical of the Northern Hemisphere also was observed, with a significant peak in the number of diagnoses occurring in October and November and a trough from April to July.[65]

A mass immunization program was initiated in Russia in 1993, with a resultant 10 percent decrease in the number of new cases reported between 1994 and 1995 (vs. twofold to threefold increases in the number of cases each year for the preceding 3 years).[57] The WHO also held training workshops and assembled laboratory kits to assist in establishing the proper diagnosis of diphtheria. As cases also began to appear in Europe with increasing frequency during this period, the European Working Group on Diphtheria (ELWGD) and reference laboratories were assembled to assist in an effort to increase routine screening for diphtheria. The ELWGD since has expanded and currently includes 20 participating countries, including representatives in Western and Eastern Europe, the United States, Australia, and Southeast Asia.[45] Surveillance from Europe from 2000 to 2009 has documented a decrease in incidence of more than 95 percent across the region, with the Russian Federation and Latvia accounting for 83 percent of the cases. In Western Europe, toxigenic *C. ulcerans* has increasingly been identified, often in association with contact with companion animals.[108]

PATHOGENESIS AND PATHOLOGY

Diphtheria is initiated by entry of *C. diphtheriae* into the nose or mouth, where the bacilli remain localized on the mucosal surfaces of the upper respiratory tract. Occasionally, the ocular or genital mucous membranes serve as the site of localization. The bacilli are unable to invade intact skin but may infect preexisting skin lesions. After a 2- to 4-day period of incubation, lysogenized strains may elaborate toxin.

Diphtheria toxin is secreted as a single polypeptide of 535 amino acids with a molecular weight of 58,342 D.[70] The toxin is composed of two subunits: a large B subunit that is involved in receptor binding and an A subunit that is the enzymatically active portion of the toxin. The toxin initially is absorbed onto the target cell membrane by binding a receptor on the cell surface and then undergoes receptor-mediated endocytosis. When it is in the endolysosomal complex, it undergoes a conformational change with subsequent release of the A subunit into the cytoplasm. The A subunit transfers an adenosine diphosphate (ADP)–ribosyl group from nicotinamide adenine dinucleotide (NAD) to elongation factor 2. This ADP-ribosylation inactivates elongation factor 2 and inhibits protein synthesis in the cell. Cholera and pertussis toxins also mediate target protein ribosylation by this mechanism. In addition to the inhibition of cellular protein synthesis, an independent mechanism of cytolysis has been described. In the presence of calcium and magnesium, diphtheria toxin has a nuclease-like activity that causes DNA fragmentation that results in cytolysis.[34,35,70,78]

Marked toxin-mediated tissue necrosis occurs in the vicinity of *C. diphtheriae* colonization and induces a robust local inflammatory response. The inflammatory response coupled with the necrotic tissue produces a patchy exudate that initially can be removed. As the infection progresses, the increased production of toxin causes a centrifugal widening of the area of infection, and eventually a fibrinous exudate develops. A tough adherent membrane results from coagulation of the exudate. The color of the pseudomembrane initially is white but over the course of time becomes dirty gray. Late in the course of the infection, green or black spots appear on the membrane, representing areas of necrosis. Histologic analysis of the pseudomembrane differs, based on the site of formation and maturation of the membrane. Analysis of the pharyngeal pseudomembrane shows fibrin; inflammatory cells, primarily composed of neutrophils, red blood cells, and colonies of organisms; and superficial epithelial cells.

With severe infections, significant vascular congestion, interstitial edema, fibrin exudate, and intense neutrophilic infiltration develop.[64] Profuse bleeding can occur when the membrane is torn off. The edematous tissue and the diphtheritic membrane may encroach on the airway. The membrane sloughs spontaneously during the recovery period, although sloughing can occur during the acute phase of the illness, leading to aspiration. Occasionally, secondary bacterial infection (classically caused by *Streptococcus pyogenes*) develops. Respiratory embarrassment or suffocation may occur, with involvement of the larynx or tracheobronchial tree. Bronchopneumonia may develop if the exudate enters the small airways and alveoli. Infection of these sites is an uncommon occurrence, however. Infections of the esophagus and stomach, with pseudomembranous lesions indistinguishable from lesions found in the respiratory tract, have been reported.[72]

Toxin produced at the site of infection is distributed throughout the body by the bloodstream and the lymphatics. This distribution occurs most readily when the pharynx and tonsils are covered by a diphtheritic membrane. Any organ or tissue can be damaged as a result of diphtheria toxin, but lesions of the heart, nervous system, and kidneys are particularly prominent. Clinical manifestations appear after a variable latent period of 10 to 14 days for myocarditis and 3 to 7 weeks for manifestations in the nervous system, such as peripheral neuritis. In a study of 102 patients who died of diphtheria caused by *C. diphtheriae*, the hearts appeared dilated, flabby, and pale, with a characteristic "streaky" appearance in the myocardium. The most prominent pathologic findings are necrosis and hyaline degeneration of the myocardium. The myocardium also appears edematous and is infiltrated with mononuclear cells with eosinophilic cytoplasm. In a significant proportion of cases, fatty accumulation in muscle fibers and the conducting system may be observed.[90] Burch and associates[22] showed mitochondrial damage with depletion of glycogen and accumulation of lipid droplets in the damaged myofibrils. Toxin may be observed within the myocardial cells with fluorescent antibody staining.[64] If the patient survives, muscle regeneration and interstitial fibrosis can be seen.

Peripheral neuropathy occurs secondary to *C. diphtheriae* infections. Histologic studies have shown that affected nerves have significant degeneration of myelin sheaths and axons. Toxic neuritis with fatty degeneration of paranodal myelin can be noted early in the disease course; segmental demyelination occurs later.[9] Axonal damage is secondary to the application of external

pressure from the swollen Schwann cell cytoplasm and myelin.[81]

C. diphtheriae infections also can lead to necrosis and hyaline degeneration of the liver, which can lead to hypoglycemia. Adrenal hemorrhage and acute tubular necrosis of the kidney have been known to occur secondary to *C. diphtheriae* infections.[64]

CLINICAL MANIFESTATIONS

The signs and symptoms of diphtheria depend on the site of infection, the immunization status of the host, and whether toxin has been distributed to the systemic circulation. The incubation period is 1 to 6 days (range, 1 to 10 days). Diphtheria can be classified clinically on the basis of the anatomic location of the initial infection and the diphtheritic membrane (nasal, pharyngeal/tonsillar, laryngeal or laryngotracheal, skin, and others) involved. More than one anatomic site may be involved simultaneously.

Nasal diphtheria initially resembles a common cold and is characterized by mild rhinorrhea and a paucity of systemic symptoms. Gradually, the nasal discharge becomes serosanguineous and then mucopurulent. A foul odor may be noticed, and careful inspection reveals a white membrane on the nasal septum. In severe cases, the infection may excoriate the nares and upper lip. Nasal diphtheria is a mild form of the disease because absorption of toxin usually is slow from this site. Frequently, delays in establishing an accurate diagnosis of nasal diphtheria occur because of the lack of systemic symptoms. The nasal form of the disease occurs most often in infants.

Pharyngeal and tonsillar diphtheria begin insidiously with anorexia, malaise, low-grade fever, and pharyngitis. Within 1 or 2 days, a membrane appears. The extent of membrane formation correlates with the immune status of the host; in some partially immune individuals, a membrane may not develop. The white or gray adherent membrane may cover the tonsils and pharyngeal walls and extend on to the uvula and soft palate or down on to the larynx and trachea. Attempts to remove the membrane are followed by bleeding. Cervical lymphadenitis varies. In some cases, it is associated with edema of the soft tissues of the neck and may be so severe that it gives the appearance of a "bull neck." In a 1970 epidemic, "erasure" edema of the neck was noted in patients with pharyngeal diphtheria.[85] Patients with erasure edema did not have a classic bull neck appearance, but the edema was characterized by obliteration of the sternocleidomastoid muscle border, the mandible, and the median border of the clavicle. The edema was brawny, pitting, warm to the touch, and tender to palpation. Erasure edema was noted in 29 percent of immunized patients and 30 percent of nonimmunized or inadequately immunized patients. It occurred most commonly in children older than 6 years and generally was associated with infection by the *gravis* or *intermedius* strain of *C. diphtheriae*.

The course of pharyngeal diphtheria depends on the degree of elaboration of the toxin and the extent of the membrane. In severe cases, respiratory and circulatory collapse may occur. The pulse rate is increased disproportionately to body temperature, which generally remains normal or slightly elevated. The palate may be paralyzed. This paralysis may be unilateral or bilateral and associated with difficulty swallowing and nasal regurgitation of swallowed fluids.[42] Stupor, coma, and death may occur within 7 to 10 days. In less severe cases, recovery may be slow and may be complicated by the development of myocarditis or neuritis. In mild cases, the membrane sloughs off in 7 to 10 days, and recovery is uneventful.

Laryngeal diphtheria generally reflects a downward extension of the membrane from the pharynx. Rarely, laryngeal diphtheria is primary and does not reflect an extension of disease from the pharynx. In these cases, toxicity and signs of toxemia generally are less prominent. Two cases of isolated diphtheritic tracheitis have been reported in the literature.[13,103] The clinical findings of laryngeal diphtheria are indistinguishable from those of other types of infectious croup. Noisy breathing, progressive stridor, hoarseness, and a dry, barking cough may be noted. Suprasternal, subcostal, and supraclavicular retractions reflect severe laryngeal obstruction, which may be fatal unless alleviated. Occasionally, in a mild case, an acute and fatal obstruction may occur because of a partially detached piece of membrane that occludes the airway. In severe cases of laryngeal diphtheria, the membrane may extend downward and invade the entire tracheobronchial tree.

Cutaneous disease, in contrast to pharyngeal disease, is more common in warmer climates and often is caused by nontoxigenic strains. In some countries with tropical and subtropical climates, such as Uganda, Tanzania, Sri Lanka, and Samoa, *C. diphtheriae* has been isolated from 60 percent of skin lesions in children.[74] Cutaneous diphtheria is more contagious than respiratory diphtheria. Cutaneous diphtheria may be an important source of person-to-person transmission of diphtheritic organisms and outbreaks in indigenous populations in which overcrowding and poor hygiene are important risk factors.[12,21,68] The skin lesions begin as vesicles or pustules that progress to typical ulcers with sharply defined borders, membranous bases, and surrounding erythema and edema. They may be covered with a dark pseudomembrane. The lesions occur most commonly on the legs, feet, and hands. For the first 1 to 2 weeks, the lesions are painful. Spontaneous healing generally takes 6 to 12 weeks, but lesions have been reported to persist for 1 year.[68]

Conjunctival, aural, and vulvovaginal diphtheria also may occur. Conjunctival lesions usually are limited to the palpebral conjunctiva, which appears red, edematous, and membranous. Rarely, conjunctival lesions have been associated with corneal erosion.[100] Diphtheria infections of the ear are characterized by the development of otitis externa with a persistent purulent and frequently foul-smelling discharge.

Clinical presentations other than typical diphtheria have been associated with isolation of the organism from patients with meningitis, endocarditis, osteomyelitis, and hepatitis. In most cases, these infections have occurred in patients with underlying problems, such as structural or valvular heart disease or intravenous drug use, or in individuals from poor socioeconomic backgrounds.[40,105]

Several cases of septic arthritis caused by nontoxigenic *C. diphtheriae* have been described.[1,63,105] Afghani and Stutman[1] reported the case of a 27-month-old child who had septic arthritis of the hip and skin lesions on the lower extremities. In this case, the skin lesions were presumed to be the portal of entry for nontoxigenic *C. diphtheriae*. Although the child had received four doses of diphtheria and tetanus toxoids and pertussis vaccines, immunization with toxoid does not provide protection against nontoxigenic strains of *C. diphtheriae*. In this case, the organism was sensitive to penicillin, cefuroxime, cephalothin, and clindamycin but was resistant to oxacillin, an antistaphylococcal antibiotic often used for the treatment of septic arthritis when the causative organism cannot be identified. A similar case was described in an immunocompetent, fully vaccinated 2-year-old child who had skin lesions from which *C. diphtheriae* was isolated. The skin lesions also were assumed to be the portal of entry for the organism because pan-sensitive *C. diphtheriae* were isolated from the skin and the articular aspirate.[64]

Within a 12-month period, in New South Wales, Australia, four cases of septic arthritis complicating endocarditis caused by the nontoxigenic *gravis* variety of *C. diphtheriae* were reported. In addition, the same strain caused three cases of endocarditis without the development of septic arthritis. Demographic distribution of these seven cases included a 12-year-old boy who died, five patients who were in their 20s, and a patient who was 49 years old. Three of the patients had underlying cardiac abnormalities, and one had a history of intravenous drug use.[105] This same clone of nontoxigenic *C. diphtheriae* was isolated from three patients in Koorie, an aborigine community in Victoria, Australia, who had endocarditis, and five asymptomatic contacts.[69] Two of the three patients with endocarditis were members of the same family, and one of them had a history of alcohol abuse. The third patient had a septic sternoclavicular joint, in addition to endocarditis, with isolation of the same organism. Nontoxigenic *C. diphtheriae* sepsis can lead to splenic and hepatic abscesses, as reported in a patient with chronic lymphocytic leukemia in British Columbia, Canada.[71]

Complications secondary to elaborated diphtheria toxin may affect any system, but myocarditis and involvement of the nervous system are most characteristic. Myocarditis may occur after mild and severe cases of diphtheria. Generally, it develops in patients in whom administration of antitoxin is delayed. Myocarditis most commonly appears in the second week of the disease, but it can appear as early as the first or as late as the sixth week of illness. Tachycardia, a muffled S_1, murmurs, and arrhythmias such as atrioventricular dissociation indicate myocardial involvement. Echocardiography may show left ventricular dysfunction.[3,61,80] Although some cases may result in cardiac failure, most myocardial complications are temporary.

Neurologic complications appear after a variable latent period. Approximately 75 percent of all patients with severe diphtheria develop neuropathies. The incidence of neurologic sequelae has been shown to correlate with the severity of respiratory symptoms; 20 percent of all patients with respiratory problems develop polyneuritis. Neurologic complications from diphtheria infections predominantly are bilateral, are motor rather than sensory, and usually resolve completely. Paralysis of the soft palate is the most common occurrence and generally appears in the third week. It is manifested by a nasal quality in the voice, nasal regurgitation, and difficulty swallowing. Ocular paralysis usually occurs around the fifth week of illness and is characterized by blurring of vision and difficulty with accommodation. Internal strabismus also may be noted. Paralysis of the diaphragm, peripheral neuropathy involving the limbs, and loss of deep tendon reflexes likewise are reported as complications of diphtheria. When they occur, along with an elevated cerebrospinal fluid protein, the syndrome is clinically indistinguishable from Guillain-Barré syndrome.

Rarely, 2 or 3 weeks after the onset of illness, involvement of the vasomotor centers results in hypotension and cardiac failure. Gastritis, hepatitis, nephritis, and hemolytic-uremic syndrome also have been reported as complications of diphtheria.[102]

Information on the effects, if any, of diphtheria on the fetus during pregnancy was unavailable until more recently. El Seed and associates[47] reported a case of pharyngeal diphtheria in a pregnant woman that occurred during the first trimester of pregnancy. Apart from vaginal bleeding, no complications of pregnancy were noted. Severe diphtheritic toxemia in the mother was characterized by quadriparesis, from which she fully recovered. A physically normal female infant was delivered at term. In this single case, severe diphtheritic toxemia during pregnancy was not associated with any teratogenic effect in the fetus and did not impair intrauterine fetal growth.

DIAGNOSIS

The diagnosis of diphtheria should be based on clinical findings because any delay in initiating therapy poses a serious risk to the patient. Isolation of the organism is used to confirm the clinical diagnosis. Material obtained from beneath the membrane, where organisms are concentrated most highly, or a portion of the membrane itself should be obtained for culture.[5,33]

C. diphtheriae is relatively resistant to drying. The use of a nonnutritive, moisture-reducing transport medium helps prevent the overgrowth of other microorganisms. The laboratory should be notified about the possibility of diphtheria so that appropriate culture media are inoculated. A Löffler slant, a tellurite plate, and a blood agar plate should be inoculated. Tellurite-containing media inhibit the growth of normal oral flora, allowing *C. diphtheriae* to grow into characteristic black colonies. Other corynebacteria, staphylococci, and yeast also can reduce tellurite and grow into black colonies.[14,38] Although examination of direct smears of colonies or diphtheritic lesions remains an important supplement to clinical examination, it often is inaccurate. Screening the colonies from the tellurite plate for catalase, urea, nitrate, pyrazinamidase, and cystinase is important. Most biotypes of *C. diphtheriae* are catalase-positive, urease-negative,

nitrate-positive (except biotype *belfanti*), pyrazinamidase-negative, and cystinase-positive.[43]

All diphtheria bacilli that are recovered should be tested for toxigenicity. In 1949, the Elek immunoprecipitation assay replaced in vivo testing for toxigenicity using guinea pigs or rabbits.[46] The Elek test is based on gel diffusion and immunoprecipitation of toxin, from organisms inoculated onto agar adjacent to an antitoxin-containing well. A strain that is positive for toxin is indicated by the formation of a precipitin band between the toxin and antitoxin.[44,46] The Elek test would take 48 hours to yield results on the toxigenic nature of a *C. diphtheriae* strain. A modified Elek test that consists of placement of an antitoxin-impregnated disk onto an agar plate surrounded by inoculates of clinical specimen and positive control has been described. In contrast to the conventional Elek test, the modified test has the advantage of using "spot" inoculations of numerous colonies directly from the primary plate. In addition, the modified Elek test has fewer false-positive and false-negative results and yields results more rapidly (16 to 24 hours).[43]

A rapid enzyme immunoassay is another test for detection of diphtheria toxin. This method uses equine polyclonal antibody to capture the diphtheria toxin and an alkaline phosphatase–labeled monoclonal antibody to detect fragment A of the toxin. It is a rapid test that takes 3 hours and has a limit of detection of 100 pg/mL.[48]

Rapid testing for diphtheria toxin by PCR specific for the "A" or "B" portion of the toxin gene, *tox*, is sensitive and has produced positive results in specimens stored for 12 months before performing the assay.* The absence of the *tox* gene by PCR excludes the diagnosis of diphtheria. PCR may give false-positive results, however, because it does not differentiate between partial or nonfunctional *tox* genes and functional *tox* gene products. An increasing number of cases of nontoxigenic diphtheria that are positive for the *tox* gene by PCR have been reported from Ukraine and Russia.[58,83]

The immune status of patients can be determined by toxin neutralization in Vero cells.[89] This method is used frequently, although it is difficult to standardize and relies heavily on individual interpretation of results. Enzyme-linked immunosorbent assay is a more rapid and quite sensitive method, but it detects some nonspecific antibodies; when antitoxin levels are in the low range, the assay may generate falsely elevated results.[86] Finally, a delayed fluorescence immune assay method was developed by Aggerbeck and colleagues[2] in 1996 and has been reported to have good sensitivity, specificity, and reproducibility.[17] Levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective. A skin-testing method, the Schick test, also has been used to assess immunity.

The Schick test was used previously to determine the immune status of the patient. It is not helpful in establishing an early diagnosis because it cannot be read for several days, and currently it is not widely used. In the Schick test, a measured amount of purified diphtheria toxin (0.1 mL) is injected subcutaneously. A hypersensitivity reaction indicates an inadequate presence of antitoxin. A toxoid control also is injected, in the opposite arm, to help distinguish between a reaction to toxin and a reaction to other antigens in the toxin preparation.

Other laboratory studies are of little diagnostic value. The white blood cell count may be normal or elevated. Rarely, anemia develops as a result of rapid hemolysis of red blood cells. Examination of cerebrospinal fluid may reveal a minimal elevation of protein and, rarely, a mild pleocytosis in patients with diphtheritic neuritis. Hypoglycemia, glucosuria, or both may occur and reflect hepatic toxicity. An elevation in blood urea nitrogen may develop in patients with acute tubular necrosis. An electrocardiogram should be obtained and may reveal ST-segment and T-wave changes or arrhythmias indicative of myocarditis.

Differential Diagnosis

Mild forms of nasal diphtheria in a partially immunized host may resemble the common cold. When the nasal discharge is more serosanguineous or purulent, nasal diphtheria must be distinguished from a foreign body in the nose, sinusitis, adenoiditis, or the snuffles of congenital syphilis. Careful examination of the nose with a nasal speculum, sinus radiographs, and appropriate serologic tests for syphilis are helpful in excluding these disorders.

Tonsillar or pharyngeal diphtheria must be differentiated from streptococcal pharyngitis. Generally, streptococcal pharyngitis is associated with more severe pain on swallowing, higher temperature, and a nonadherent membrane limited to the tonsils. In some patients, pharyngeal diphtheria and streptococcal pharyngitis coexist.

Tonsillar and pharyngeal diphtheria also must be differentiated from infectious mononucleosis (lymphadenopathy and splenomegaly are common findings, atypical lymphocytes are generally present, and heterophile antibody may be present), nonbacterial membranous tonsillitis (white blood cell count generally is low, throat cultures reveal normal flora, and the course is unaffected by antibiotics), primary herpetic tonsillitis (presence of gingivitis, stomatitis, and discrete lesions of the tongue and palate may be helpful), Vincent angina (may be indistinguishable), and thrush (constitutional symptoms are absent, and lesions are present on the buccal mucosa and tongue). Tonsillar and pharyngeal diphtheria also must be differentiated from blood dyscrasias such as agranulocytosis and leukemia (complete blood count and bone marrow study are helpful); post-tonsillectomy faucial membranes (membranes are stationary and do not spread); and oropharyngeal involvement by toxoplasmosis, *Arcanobacterium*, cytomegalovirus, tularemia, and salmonellosis (associated signs and symptoms and appropriate cultures and serologic tests may be diagnostic).[55]

Laryngeal diphtheria must be differentiated from spasmodic or nonspasmodic croup; acute epiglottitis; laryngotracheobronchitis; aspirated foreign bodies; peripharyngeal and retropharyngeal abscesses; and laryngeal papillomas, hemangiomas, or lymphangiomas. A careful history, followed by careful visualization in the hospital under controlled conditions, aids in making a correct diagnosis.

PREVENTION

Diphtheria is prevented on a community-wide basis most effectively by active immunization. Diphtheria toxoid is available in combination with tetanus toxoid as pediatric DT or adult Td and in combination with acellular pertussis as DTaP and Tdap. Combination regimens with DTaP and inactivated poliovirus and hepatitis B (Pediatrix) and inactivated poliovirus and *Haemophilus influenzae* type B (Pentacel) are also available. Pediatric formulations of diphtheria toxoid vaccines contain three to four times more diphtheria toxoid but the same tetanus toxoid in contrast to the adult formulations. Children younger than 7 years should be given the pediatric formulations of vaccine, whereas children older than 7 years should receive the adult Td. Two forms of Tdap are available: Boostrix, which is approved for children beginning at age 10 through 65 years or older, and Adacel, which is approved for individuals 11 to 64 years old.[23,27-30]

Primary immunization is carried out conveniently and effectively by giving diphtheria and tetanus toxoids and pertussis vaccine, DTaP, at 2, 4, and 6 months of age, with booster doses given at 15 to 18 months and again when the child is 4 to 6 years of age. Booster doses with the adult type of diphtheria and tetanus toxoids adsorbed (Td) should be given at 10-year intervals to all immunized individuals. Current recommendations are to give Tdap as the first booster dose in patients who are 11 to 12 years old and to anyone older who has not received a dose of Tdap.[31] Td and Tdap contain 2 to 2.5 flocculation units (Lf) diphtheria toxoid per dose in contrast to 7 to 25 Lf in the pediatric diphtheria, tetanus toxoid, and pertussis vaccine preparations (DTaP and DT). Primary immunization of children older than 7 years may be performed with Td. Two doses are given intramuscularly at least 4 weeks apart, with a booster dose provided 1 year later. Children and adults who are severely immunocompromised or undergoing long-term hemodialysis should use the standard immunization schedule, although response may be suboptimal.[51,56,76]

Most local and systemic reactions to the diphtheria and tetanus toxoids and whole cell pertussis vaccine (DTP), including fever, were related to the pertussis component.[10,37] Administration of tetanus and diphtheria toxoids is not followed by the high incidence of reactions associated with the use of pediatric DTP vaccines. At least one study showed that 7.5 Lf toxoid can be given safely to adults without a higher risk for reactions occurring.[15] Primary immunization against diphtheria for infants with progressive neurologic disorders and completion of the primary immunization series in patients who had experienced an untoward reaction to an earlier DTP vaccine injection may be performed with diphtheria and tetanus toxoids rather than diphtheria and tetanus toxoids and pertussis vaccine.[4]

A report of 97 preterm infants who received diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) (94 of these infants also received *H. influenzae* type b vaccine) showed that most infants tolerated the vaccination without side effects, although a subgroup of infants with very low birth-weight (mean, 873 g) had either a recurrence or an increase in the number of apneic and bradycardic episodes in the 48 hours after receiving vaccination. The apneic and bradycardic episodes were present before immunization in every case.[101]

Booster doses of tetanus and diphtheria toxoids should be given at 10-year intervals to all immunized individuals. The Centers for Disease Control and Prevention Advisory Committee on Immunization Practices now recommends that all adults aged 19 years and older who have not received a dose of Tdap should receive a single dose.[32,84] As mentioned earlier, levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective.

Diphtheria immunization is not always followed by complete protection.[88] Immunization is directed against the phage-mediated toxin, not against infection. Fully immunized individuals may be carriers or may have disease caused by nontoxigenic strains. An investigation conducted during an epidemic in Texas showed no statistical difference in the risk for diphtheria infection developing in individuals with full, lapsed, inadequate, or no previous diphtheria immunization; however, a 30-fold increased risk for development of symptomatic diphtheria in individuals with no immunization and an 11.5-fold increase in individuals with inadequate immunization were noted.[88]

The most important health problem in the United States today is inadequate immunization of the population. Immunization rates in adults are poorer than those in infants and children because of failure to maintain adequate immunity through appropriate booster immunization. A 70 to 80 percent immunization level is thought to be required to prevent epidemic spread.[36]

Prevention of diphtheria also depends on management of the contacts of known cases of diphtheria and carriers of the organism and on isolation of patients to minimize the spread of disease. Individuals at risk for contracting the disease from the index case include those who have had close respiratory or physical contact or prolonged close proximity with the infected individual, including members of the index case's household.[18] Specifically, family members who share body towels and cups or eating utensils, share a bed or a bedroom with more than two people, or take a bath less than once per week have a significantly greater risk for contracting the disease from the infected patient. A history of eczema in the contact also has been associated with a significantly increased risk for contracting diphtheria from the index case.[98] The patient is infectious until diphtheria bacilli no longer can be cultured from the site of infection. Two or three consecutive negative cultures at least 24 hours apart are required, and antibiotic therapy must be complete for 24 hours before the patient is released from isolation. If obtaining cultures is impossible, isolation may be ended after the completion of 14 days of appropriate antibiotic treatment.[6]

Cultures should be taken from the nose and throat of all close contacts, who should be kept under surveillance for 7 days (surveillance as an outpatient is acceptable).[5] Regardless of their immunization status, contacts should

be treated with a single intramuscular dose of benzathine penicillin G 600,000 U for individuals weighing less than 30 kg and 1.2 million U for individuals weighing more than 30 kg or a 7-day course of erythromycin 40 to 50 mg/kg/day (maximum 2 g/day) divided into four doses.[5] The immune status of each contact should be determined; individuals for whom immune status is inadequate, including individuals who have had the primary series but more than 5 years has elapsed since they received their last booster dose, should receive an injection of diphtheria toxoid. In addition, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.[6]

Asymptomatic carriers who previously were not immunized against diphtheria should have cultures taken, receive diphtheria toxoid and penicillin or erythromycin (as described earlier), and be seen daily by a physician. Asymptomatic contacts who are found to carry a toxigenic strain should be subjected to the same isolation and treatment measures as the index case.[6] If daily surveillance is impossible, benzathine penicillin is preferred over erythromycin for treatment because failure to adhere to an oral drug regimen is a concern. If a contact is experiencing symptoms when seen, treatment of diphtheria is indicated. It is important to initiate prophylactic therapy in contacts who have not been immunized, before the results of culture are received. Management of carriers is described in the next section. Contacts whose occupations involve close contact with unimmunized children or food handling (especially milk) should refrain from working until cultures are confirmed to be negative.[6]

TREATMENT

Treatment of diphtheria is predicated on neutralization of free toxin and eradication of *C. diphtheriae* or *C. ulcerans* with antibiotics. Disease caused by *C. ulcerans* should be treated in the same manner as disease caused by *C. diphtheriae*.[3,25] The decision to administer equine antitoxin should be based on the site and size of the membrane, the degree of toxicity, and the duration of illness.[16]

Antitoxin can neutralize circulating toxin or toxin that is absorbed onto cells, but is ineffective when cells have been penetrated. Early treatment is essential to limit tissue damage. An adequate dose of antitoxin must be administered intravenously as early as possible to neutralize all free toxins. A single dose is used to avoid the risk for developing sensitization from repeated doses of horse serum. Tests for sensitivity to horse serum must be performed before antitoxin is administered. For this purpose, 0.02 mL of a 1:1000 dilution of antitoxin in saline can be given intracutaneously. Positive (histamine) and negative (isotonic saline) controls should be applied similarly. A positive reaction consists of a wheal at least 3 mm larger than the negative control, with surrounding erythema at the site of injection, developing within 15 to 20 minutes, and necessitates desensitization. The histamine control must be positive if test results are to be considered valid. Alternatively, the test may be done with a drop of serum diluted 1:100 and applied to the site of a superficial scratch, prick, or puncture on the volar aspect of the forearm. Controls should be applied and results interpreted as described for intracutaneous administration.[5]

If a patient has been shown to be sensitive to horse serum, the serum should be provided in a slowly increasing dosage given at 15-minute intervals. Several regimens have been used. One recommended regimen is as follows[5]:

- 0.1 mL of a 1:1000 dilution intravenously
- 0.3 mL of a 1:1000 dilution intravenously
- 0.6 mL of a 1:1000 dilution intravenously
- 0.1 mL of a 1:100 dilution intravenously
- 0.3 mL of a 1:100 dilution intravenously
- 0.6 mL of a 1:100 dilution intravenously
- 0.1 mL of a 1:10 dilution intravenously
- 0.3 mL of a 1:10 dilution intravenously
- 0.6 mL of a 1:10 dilution intravenously
- 0.1 mL undiluted intravenously
- 0.3 mL undiluted intravenously
- 0.6 mL undiluted intravenously
- 1 mL undiluted intravenously

The intravenous route for desensitization is considered safest because it offers good control, but protocols involving the intradermal, subcutaneous, and intramuscular routes also have been used frequently.[5]

If no reaction has occurred, the remaining material is given by slow intravenous infusion. Intravenous administration results in more rapid excretion of antitoxin into saliva, rendering it atoxic and preventing further absorption of toxin in the oropharynx, but it does not result in more rapid systemic elimination of antitoxin than intramuscular administration.[104] Reactions should be treated with aqueous epinephrine (1:1000) provided intravenously.

The antitoxin dosage is empirical. Pharyngeal or laryngeal disease of 48 hours' duration or less should be treated with 20,000 to 40,000 U, nasopharyngeal disease with 40,000 to 60,000 U, and severe pharyngeal or laryngeal diphtheria with 80,000 to 120,000 U of antitoxin. The last dose also should be given to patients with mixed clinical symptoms and to patients with brawny edema or disease of longer than 48 hours' duration. The value of antitoxin in the treatment of cutaneous disease is debated, but some experts recommend 20,000 to 40,000 U because toxic effects have been reported.[5]

Although antibiotics are not a substitute for treatment with antitoxin, they should be given when diphtheria is suspected clinically. Penicillin and erythromycin are still effective against most strains of *C. diphtheriae*. Penicillin and erythromycin also are effective in eradicating group A hemolytic streptococci, which may complicate 30 percent of cases of diphtheria. Treatment consists of a 14-day course of penicillin or erythromycin. Penicillin may be given as aqueous penicillin G 100,000 to 150,000 U/kg/day in four divided doses intravenously or as procaine penicillin 25,000 to 50,000 U/kg/day (maximum of 1.2 million U) in two divided doses intramuscularly. Patients who are sensitive to penicillin should be given erythromycin in a daily dosage of 40 to 50 mg/kg (maximum of 2 g/day) in four divided doses for 14 days. When the patient is able to tolerate oral

medications, erythromycin or penicillin V may be used in place of the intravenous antibiotics.[5]

Follow-up cultures should be obtained at least 2 weeks after antibiotic therapy is completed; if they are positive, erythromycin should be given for an additional 10 days.[5] Some resistance to erythromycin has been observed, but it is uncommon, and its epidemiologic significance is unknown.[5,6] Penicillin is recommended as first-line treatment in Vietnam, based on sensitivity data.[73] Amoxicillin, rifampin, and clindamycin provided in appropriate dosages also may be effective. Lincomycin and tetracycline have proved to be less effective, and cephalexin, oxacillin, and colistin have been shown to be ineffective against *C. diphtheriae*. The end point of therapy is two or three consecutive negative cultures at least 24 hours apart. In addition to receiving antibiotic therapy, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.[5]

The carrier state has been treated effectively with a single intramuscular dose of benzathine penicillin G 600,000 U for children weighing less than 30 kg or 1.2 million U for individuals weighing 30 kg or greater or oral erythromycin 40 to 50 mg/kg/day for children and 1 g/day for adults for 7 to 10 days.[5] Carriers should have repeat pharyngeal cultures performed a minimum of 2 weeks after antibiotic therapy is complete; if the repeat cultures are positive, carriers should receive an additional course of antibiotics.

Treatment of deep infections caused by nontoxigenic *C. diphtheriae* can be accomplished with a wide variety of susceptible agents. Endocarditis with these organisms treated with either a β-lactam alone or in combination with an aminoglycoside has been associated with favorable outcomes.[91]

Supportive Treatment

Bed rest is extremely important and should be required for 2 to 3 weeks. Serial electrocardiograms should be obtained two or three times each week for 4 to 6 weeks to detect myocarditis as early as possible. Absolute bed rest must be enforced if myocarditis is detected, because sudden death has been precipitated by excessive activity. A patient with myocarditis may receive digitalization if congestive heart failure develops. Digitalization for arrhythmias caused by diphtheria may be contraindicated, however. In severe disease, prednisone 1 to 1.5 mg/kg/day for 2 weeks has been shown to lessen the incidence of myocarditis.

Hydration should be maintained, and a high-calorie liquid or soft diet should be provided. Secretions should be suctioned as needed to prevent aspiration. Palatal and pharyngeal paralysis increases the risk for aspiration occurring, so gavage via a nasogastric tube is indicated in these patients.

The quality of the voice and the gag reflex should be checked regularly for assessment of progression of the disease. Laryngeal diphtheria may require relief of obstruction with a tracheostomy. This procedure should be performed before the patient has become exhausted.

Adequate immunity does not develop in at least half of patients who recover from diphtheria, and they remain subject to reinfection. Immunization is indicated after the patient recovers.

PROGNOSIS

Many factors affect the prognosis in cases of diphtheria, the most important being the immunization status of the host. Morbidity and mortality rates are increased significantly in patients who are unimmunized or inadequately immunized. The rapidity with which medical care is sought and the diagnosis of diphtheria is suggested has a great impact on outcome. If specific treatment is provided on the first day of disease, the mortality rate may be reduced to less than 1 percent; delay in providing treatment until day 4 may be associated with a 20-fold increase in the mortality rate.

The virulence of the infecting organism and the location of infection are important prognostic factors. Infection with a nontoxigenic *C. diphtheriae* strain may cause disease but does not lead to myocarditis, neuritis, and other toxin-related phenomena. Toxigenic disease may vary from mild to severe. In cases of mild diphtheria, membrane sloughing and full recovery generally occur within 7 days. Disease caused by toxigenic *gravis* strains tends to be more severe and carries a poorer prognosis. Although diphtheria may affect the skin, nasopharynx, and other mucous membranes, involvement of the larynx heralds a more complicated course. Laryngeal diphtheria increases the risk for development of airway obstruction and promotes systemic absorption of the toxin. These patients require close monitoring of respiratory function and for involvement of other organ systems. Laryngeal diphtheria is more likely to be fatal in infants.

Few laboratory parameters indicate the severity of diphtheria. The development of amegakaryocytic thrombocytopenia and leukocytosis with counts of greater than 25,000 cells/mm^3 has been associated with a poor outcome.

The prognosis in a patient with diphtheria remains guarded until recovery is complete. At any time during the course of the illness, complications such as laryngeal obstruction, shock, and ventricular fibrillation may occur suddenly and unexpectedly. In patients with myocardial involvement, permanent damage to the heart, specifically fibrosis, may occur and lead to later complications. In addition, potentially severe neurologic manifestations, such as phrenic nerve paralysis, may appear late in the course of the disease.

Persistence of *C. diphtheriae* may be noted in the nasopharynx of 5 to 10 percent of convalescing patients. Recovery from diphtheria is followed by immunity that is demonstrable for at least 1 year after illness in 50 percent of patients. Second attacks are rare; nonetheless, immunization should be performed after the patient recovers.

Before the use of antitoxin and the availability of antibiotics, the mortality rate from diphtheria was 30 to 50 percent. Death was most common in children younger than 4 years old and was the result of suffocation. At present, the worldwide mortality rate is 5 to 10 percent, with no clear association with age.

CHAPTER 91

Anthrax

Morven S. Edwards

Anthrax is a toxigenic disease of herbivores for which humans are an incidental host. The term *anthrax*, derived from the Greek *anthrakos*, which means "coal," refers to the black eschar characteristic of cutaneous anthrax. The three clinical manifestations of anthrax are cutaneous, which accounts for 95 percent of infections in the United States; inhalational; and gastrointestinal. Each manifestation can occur in children,[29,42] and all can be complicated by meningitis.

HISTORICAL ASPECTS

Anthrax has been recognized since antiquity. The earliest reference to a disease thought to be anthrax is a description in Exodus of the plague that caused the death of all of the Egyptians' cattle. Hippocrates described carbuncles that are thought to represent the cutaneous form of anthrax. An account of anthrax in animals is detailed in the third of the Roman poet Virgil's four *Georgics*.[39] In the early 17th century, an anthrax pandemic referred to as the "Black Bane" caused 60,000 human deaths in Europe. By the 18th century, several excellent descriptions of the clinical disease in humans had been published.

Bacillus anthracis has a unique niche in infectious diseases. The organism, seen microscopically by Delafond in 1838, was isolated and cultivated in 1877 by Koch, who showed its proliferation in vivo, establishing a model for the causation of infectious disease. In 1881, both Pasteur and Greenfield[45] showed that a live-attenuated anthrax bacillus vaccine protected against subsequent challenge in animals, demonstrating the efficacy of immunization to prevent an infectious disease. In the late 1800s, anthrax was proved to be the cause of woolsorter's disease, or inhalation anthrax, contracted by factory workers handling anthrax-contaminated animal hides.

During World War I, *B. anthracis* was manufactured as an agent for biologic warfare. Because anthrax transmitted by inhalation is usually fatal and because *B. anthracis* spores are stable in the environment, anthrax continues to be a focus of biologic warfare research programs. The accidental release of anthrax spores from a military research facility in Sverdlovsk in the former Soviet Union in 1979 resulted in at least 68 deaths from inhalational anthrax.[32]

The first confirmed outbreak associated with intentional anthrax release in the United States occurred in October and November 2001.[22] Anthrax spores were disseminated by mail, resulting in 5 deaths from inhalation and 22 total cases of cutaneous and inhalational anthrax. Envelopes containing anthrax spores were sent through the U.S. Postal Service to offices of newspaper and broadcast media and U.S. senators. The spores were "weaponized," or finely milled, and treated with chemicals to prevent clumping so that they dispersed when the envelopes were opened and leaked from sealed envelopes as they passed through mail-sorting machines. A single anthrax strain was implicated. Outbreak-related expenditures exceeded billions of dollars, and the outbreak revealed the potential impact of a bioterrorism event on society.[6,10] It is estimated that the aerosolized release of

100 kg of anthrax spores upwind of Washington, D.C., could result in 130,000 to 3 million deaths.

BACTERIOLOGY

B. anthracis is an aerobic, nonmotile, spore-forming rod in the family Bacillaceae. Optimal growth occurs at 36° C in nonselective media. Colonies are gray-white, rough, and flat and can have comma-shaped projections caused by the outgrowth of chains of bacilli from the edges of the colony, giving it a "Medusa head" appearance. Individual colonies are 4 to 5 mm in diameter with a ground-glass appearance and exhibit tenacity or a "beaten egg white" appearance when lifted with an inoculating loop. The capsule, a γ-linked poly-D-glutamic acid, can be produced in blood or by culture in carbon dioxide. Gram stain of clinical material reveals large, square-ended, gram-positive rods singly or in short chains without a visible capsule. The equatorial or paracentral spores are invisible in smears fixed promptly after collection. After 24 to 48 hours of aerobic incubation, strands of rods are arranged in "boxcar" or "bamboo" fashion and sporulation occurs. Small numbers of bacteria are pathogenic for mice, guinea pigs, and rabbits, and death usually occurs 2 to 5 days after inoculation. Genotyping methods are available to determine molecular relatedness of clinical isolates and their geographic origin.[30]

EPIDEMIOLOGY AND TRANSMISSION

Domestic herbivores—cattle, sheep, horses, goats, and swine—are the most important agricultural sources of anthrax, but all domestic and many wild animals can serve as hosts. Animals are infected by ingestion of spores from infected pastures. Spores germinate in vivo, and death, associated with massive septicemia, usually occurs in 1 or 2 days. Anthrax is endemic in areas where an animal–soil–animal cycle is established because the spores can survive indefinitely in a dry environment. Uncultivated soil with a pH greater than 6.0 and ambient temperature greater than 15.5° C provides an environment favorable for persistence of spores.[47]

An estimated 20,000 to 100,000 human cases of anthrax occur yearly.[40] Regions of high endemicity include South and Central America, southern Europe, eastern Europe, Asia, Africa, the Caribbean, and the Middle East. The number of human cases probably correlates with the enzootic status of the disease in livestock in these countries. Familial clustering can occur in association with exposure to diseased animals.[35] Children who live in endemic areas often contract cutaneous anthrax from direct animal contact.[34] More than half of 448 patients from the Gambia with cutaneous anthrax were younger than 15 years of age, and 11 percent were younger than 2 years of age.[20] Epizootics of anthrax occur in the lower Mississippi valley and in parts of California, Texas, Missouri, Nebraska, and South Dakota[48]; sporadic cases have occurred in almost every state. Cases of illness were identified in four states and in Washington, D.C., during the 2001 bioterrorism-related outbreak.

The incidence of human anthrax in the United States has decreased markedly since the early 1900s, when more than 100 cases were reported annually. Cutaneous infections are reported sporadically. Cases often are associated with exposure to contaminated animal products in commercial preparations, but exposure to indigenous animal anthrax does occur.[43] Two members of a farmer's family ate hamburgers made from an anthrax-infected steer in Minnesota in 2000. The family members received antibiotic prophylaxis and anthrax vaccine and remained well.[11]

Direct contact with contaminated animal meat or carcasses or with contaminated animal products, such as hides, hair, wool, bone meal, and animal feed, are sources of transmission of anthrax spores to humans. Children of industrial workers have acquired infection, presumably from contact with their parents' contaminated clothing. Processed products, such as shaving brushes and saddle blankets, have been implicated as sources of infection. Use of contaminated goat hides from West Africa caused cutaneous anthrax in a drum maker in Connecticut and, through his work clothing or objects from his shed, led to cutaneous anthrax in his 8-year-old child.[13] Cutaneous anthrax is transmitted by deposition of spores or bacilli into abrasions or cuts in the skin. Blood-sucking insects, including mosquitoes and stable flies, can be vectors.[31,46,47]

The specific mode of acquisition may be difficult to determine in children; in one child with cutaneous anthrax, the only potential exposure was proximity to a bone meal factory that he walked past on his way to school.[26] Tying the umbilicus with a dirty thread was the presumed portal of entry for a neonate with *B. anthracis* sepsis.[34] Rubbing with contaminated fingers or deposition by an insect vector can lead to cutaneous involvement of the eyelids.[50] Discharge from cutaneous lesions theoretically is infectious, but person-to-person transmission has not been confirmed. Skin-to-skin contact through his mother's exposure at her workplace was proposed as the route of transmission to an infant in the bioterrorism-related outbreak in the United States in 2001.[19] Maternal anthrax has been associated with preterm delivery.[23]

Inhalational anthrax results from inhalation of spores. The estimated infectious dose in humans is 8,000 to 50,000 spores. Cases of inhalational anthrax in the United States have occurred in a weaver whose imported yarn was contaminated and in a drum maker whose imported hand-dried animal hide was contaminated with *B. anthracis*.[8,12] Eleven adults acquired inhalational anthrax during the 2001 bioterrorism outbreak of anthrax in the United States. Gastrointestinal anthrax usually is caused by ingestion of contaminated meat but also has occurred after exposure to a contaminated animal-hide drum.[15,24] A neonate was reported to have contracted anthrax meningitis from his mother, who was septicemic at the time of delivery.[20]

PATHOGENESIS AND PATHOLOGY

Anthrax toxicity results from the capsule and from the activity of three polypeptides—protective antigen, edema

factor, and lethal factor—that combine to form two exotoxins: lethal toxin and edema toxin. Protective antigen is integral to the action of both toxins. Toxin entry into cells is initiated when protective antigen binds to membrane receptors of susceptible cells. Two related proteins, tumor endothelial marker 8 and capillary morphogenesis protein 2, function as receptors. Cleaved protective antigen oligomerizes, and a heptamer of protective antigen provides binding sites for edema factor or lethal factor. The complex is endocytosed as edema toxin or lethal toxin.

Edema factor is a calmodulin-dependent adenylate cyclase that increases intracellular cyclic adenosine monophosphate levels and is responsible for the massive edema that occurs in cutaneous anthrax.[27] Lethal factor is a metalloproteinase that cleaves mitogen-activated protein kinase kinases so that they are unable to activate their downstream substrates, the mitogen-activated kinases.[18] Lethal factor stimulates production of tumor necrosis factor-α and interleukin-1β. The capsule of *B. anthracis* contributes to virulence by inhibiting phagocytosis.[22,49]

Cutaneous infection is initiated when anthrax spores are ingested at the site of entry by macrophages and germination occurs in skin tissues. Production of toxin results in local edema. Regional lymphangitis and lymphadenopathy can occur.[16] Interstitial edema, lymphatic dilation, and thrombosis and necrosis of blood vessels are characteristic microscopic features of cutaneous anthrax lesions. Erythrocytes extravasate freely into interstitial fluid. Few neutrophils or other inflammatory cells are present unless a lesion is infected secondarily. Hemorrhagic lymphadenitis involving regional lymph nodes occurs in all forms of anthrax.

In inhalation anthrax, spores entering the alveoli are ingested by alveolar macrophages and dendritic cells and carried to mediastinal lymph nodes, where they germinate. Inhalation anthrax is not pneumonia, although primary focal hemorrhagic necrotizing pneumonia can occur at the pulmonary portal of entry.[1] Massive hemorrhagic mediastinal lymphadenitis can block lymphatic drainage routes and can be causally related to the pulmonary edema, respiratory distress, and systemic disease observed clinically.

Gastrointestinal anthrax results from ingestion of spores or vegetative bacilli in contaminated meat. The primary sites of infection are the epithelium of the stomach or bowel wall.[7] Edema and small necrotic ulcers of the mucosa of the gastrointestinal tract, especially the ileum or cecum, are characteristic findings. Dissemination to the central nervous system can occur by hematogenous or lymphatic routes from any site of primary involvement. Hemorrhage involving the meninges and intense arteritis are uniform findings in patients who die of anthrax meningitis.

CLINICAL MANIFESTATIONS

Cutaneous Anthrax

The lesions of cutaneous anthrax occur mainly on exposed areas of the body.[2] In one report, the distribution in young children was 52 percent of lesions on the head and neck, 28 percent on the trunk, and 20 percent on the extremities, whereas in older children the distribution was 70 percent on the head and neck, 16 percent on the trunk, and 14 percent on the extremities.[21] Spores are introduced through abraded or injured skin. Children can have one or several lesions, and they are associated with regional adenitis.[28] After an incubation period of 2 to 5 days, a small, nontender, but frequently pruritic, papule develops at the site of inoculation. The lesion progresses to a serous or serosanguineous vesicle with surrounding nonpitting edema within 36 hours. Satellite vesicles, sometimes referred to as a "pearly wreath,"[50] can be seen occasionally.

The lesion undergoes central necrosis, and a 1- to 3-cm black eschar with well-defined margins forms 1 week to 10 days after onset of illness (Fig. 91-1).[38] The term *malignant edema* is used to describe severe lesions,

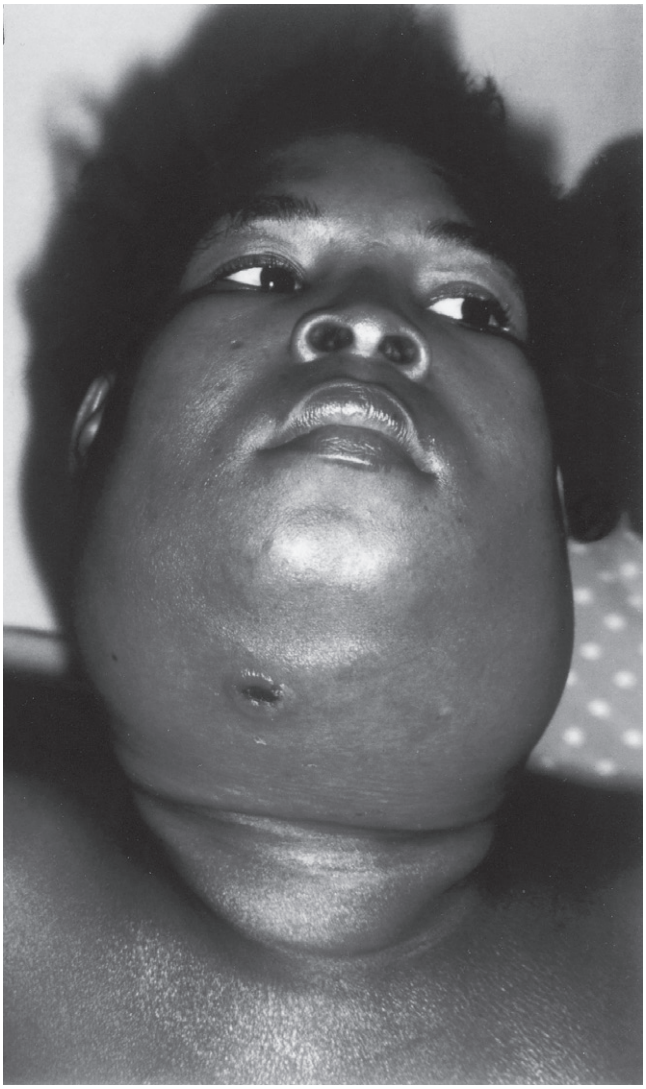

FIGURE 91-1 ■ Cutaneous anthrax with associated massive submental edema. The lesion is located at the site of a small, initially trivial laceration that served as the portal of entry for the anthrax endospores. The patient received ampicillin and recovered completely. (Courtesy M. Thomas Casey, MD.)

particularly lesions involving the head and neck, which can be associated with systemic toxicity and occlusion of the airway. Small children can appear acutely ill with a temperature of 39° to 40°C (102.2° to 104°F) and leukocytosis with counts of 20,000 to 30,000 cells/mm^3.[19,26] Associated bacteremia is uncommon. The edema usually resolves within 2 to 3 days, but separation of the eschar can take several weeks, and healing occurs with variable central scarring.

Inhalational Anthrax

Inhalational anthrax is a biphasic illness. Symptoms in the initial stage—malaise, low-grade fever, myalgia, and nonproductive cough—are nonspecific and resemble the symptoms of an upper respiratory tract illness. Adults who have inhalational anthrax are more likely to present with tachycardia, high hematocrit, and low albumin and sodium levels and are less likely to present with myalgias, headache, and nasal symptoms than are adults who have influenza-like illnesses.[25] After several days of illness, dyspnea and hypoxemia initiate onset of the second stage, which usually terminates fatally within 24 hours. Chest radiographs can show a widened mediastinum with smooth borders and evidence of hemorrhagic mediastinitis and pleural effusions. The pleural effusions often are large and usually contain bloody fluid. Pulmonary infiltrates usually are the result of superimposed bacterial infection. In the more recent cases from the United States, computed tomography of the chest showed the characteristic findings of hemorrhagic mediastinal and hilar lymph nodes and mediastinal edema and pleural effusions.[6]

Gastrointestinal Anthrax

Gastrointestinal anthrax can manifest as oropharyngeal or intestinal manifestations.[9] Each has an incubation period of 2 to 5 days after the ingestion of contaminated meat. The oropharyngeal form results in an oral or esophageal ulcer.[7,22,37] Presenting features include fever, severe sore throat, neck swelling caused by edema and enlargement of the cervical lymph nodes, dysphagia, and respiratory difficulty. Lesions on the tonsils or posterior oropharynx progress over 1 to 2 weeks from edema to a pseudomembrane-covered ulcer. The oropharyngeal form of anthrax, although uncommon, has a more favorable prognosis than does intestinal anthrax.

Initial features of intestinal anthrax are fever, nausea, anorexia, vomiting, and diffuse abdominal pain that progresses rapidly to severe abdominal pain with rebound tenderness. Vomiting of blood-tinged or coffee ground–like material and melena are common and are secondary to ulceration of the intestinal mucosa.[7,22,33] The pain decreases, and massive ascites develops within 24 to 48 hours of onset. Abdominal radiographs at this time show edematous loops of bowel and decreased air. If the abdomen is explored, findings include enlarged, erythematous mesenteric lymph nodes and straw-colored to purulent ascitic fluid in which organisms are readily visible.[3] Death usually occurs in association with significant blood loss, fluid and electrolyte imbalance, and shock. If the patient survives, the edema and melena subside in 10 to 14 days.

Meningitis

Most reports of anthrax meningitis are associated with cutaneous disease, likely owing to the higher frequency of cutaneous disease. Anthrax can disseminate to the meninges from any site of primary involvement. In the 2001 bioterrorism event, one adult with inhalation anthrax presented with meningitis and several others had features suggestive of central nervous system involvement.[36] In a report of 70 patients with anthrax meningitis who ranged from younger than 1 to 71 years of age, no primary focus was evident in 12 percent.

Anthrax meningitis is characterized by a fulminant, rapidly progressive course. Initial symptoms include intense headache, nausea and vomiting, myalgia, chills, dizziness, and, occasionally, a petechial rash. Meningismus is usually, but not invariably, present because of the acuity of the course. Progressive neurologic deterioration with delirium, convulsions, and coma can occur in hours or over 2 to 4 days. Overall survival is approximately 5 percent, but survival without sequelae has been reported in at least three children, two of whom had cutaneous lesions at diagnosis.[36,41,42,44]

Examination of cerebrospinal fluid reveals (1) gross or microscopic hemorrhage, (2) leukocytosis consisting predominantly of polymorphonuclear leukocytes, (3) elevated protein level, and (4) depressed glucose level. Gram-positive rods are easily visible on smears of cerebrospinal fluid. Peripheral leukocytosis is common, and the white blood cell count can be 60,000 to 80,000 cells/mm^3. Blood cultures yield the organism in 70 percent, and cerebrospinal fluid cultures are positive in virtually 100 percent of patients.[20] Neuroimaging findings are notable for multiple hemorrhages in the ventricles, subarachnoid space, and deep gray matter.[36]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

B. anthracis can be visualized by direct smear and cultured from tissue biopsy specimens or discharge from cutaneous lesions and from pleural fluid, blood, and cerebrospinal fluid in systemic infections. The commercially available QuickELISA Anthrax-PA Kit can be used as a screening test.[4] Definitive identification of suspected isolates can be obtained through the Laboratory Response Network in each state. Time-resolved fluorescent assay, real-time polymerase chain reaction, serologic tests to detect antibodies against protective antigen, and tissue immunochemistry are available through state health departments. The enzyme-linked immunosorbent assay used to detect IgG to *B. anthracis* protective antigen is

highly sensitive, has good specificity, and yields a positive result 10 days after the onset of symptoms.[6]

The lesion of cutaneous anthrax must be differentiated from ecthyma gangrenosum and from ulcerative skin lesions with regional lymphadenopathy, including rat-bite fever, ulceroglandular tularemia, plague, glanders, scrub typhus, rickettsialpox, cowpox, and orf. Staphylococcal lymphangitis can be distinguished by the discharge of purulent material and by the inflammatory response observed microscopically. Noninfectious causes of eschars include arachnoid bites and vasculitides.[22] The first stage of inhalational anthrax and the clinical features of the intestinal form are nonspecific, so a history of exposure is crucial to establishing the diagnosis. The mediastinal widening that occurs early in the course of inhalational anthrax can cause confusion with that seen in acute bacterial mediastinitis and in fibrous mediastinitis caused by *Histoplasma capsulatum*.[16] Gastrointestinal anthrax must be differentiated from other causes of acute abdominal illness and, if bleeding is present, from duodenal ulcer, typhoid, and intestinal tularemia. Anthrax meningitis must be differentiated from subarachnoid hemorrhage.[20]

TREATMENT

Most strains of naturally occurring *B. anthracis* are susceptible to penicillin and tetracycline, and treatment for 7 to 10 days is adequate. Treatment of bioterrorism-associated cutaneous disease should be initiated with ciprofloxacin 30 mg/kg per day orally divided every 12 hours, not to exceed 1000 mg every 24 hours, or doxycycline 100 mg orally two times per day for children 8 years of age or older or 4.4 mg/kg per day divided every 12 hours, not to exceed 200 mg per day for children younger than 8 years of age until susceptibility data are available. The antimicrobial regimen should continue for 60 days to provide postexposure prophylaxis and should be administered in conjunction with vaccine as indicated (see later).[4]

The initial regimen for treatment of inhalational anthrax, gastrointestinal anthrax, anthrax meningitis, or cutaneous anthrax with systemic signs should include intravenously administered ciprofloxacin 400 mg every 8 to 12 hours. One or two additional antimicrobial agents should be administered in conjunction with ciprofloxacin. Suggested agents with in vitro activity include penicillin, ampicillin, clindamycin, vancomycin, rifampin, meropenem, chloramphenicol, and clarithromycin.[17] Fluoroquinolones other than ciprofloxacin, including levofloxacin, also have excellent in vitro activity against *B. anthracis*. Therapy should be continued for at least 60 days.

For severe anthrax, Anthrax-Specific Hyperimmune Globulin 5 percent should be considered in consultation with the U.S. Centers for Disease Control and Prevention under an emergency investigative new drug (IND) proposal.[4] Supportive therapy includes attention to details of fluid and electrolyte balances, endotracheal intubation if indicated to maintain a patent airway, and local care for cutaneous lesions. Systemic corticosteroids can reduce the severity of infections in patients with massive edema or meningitis.[42]

PROGNOSIS

Before penicillin was introduced, cutaneous anthrax was fatal in approximately 20 percent of patients. With effective treatment, the mortality rate is less than 1 percent. Cutaneous anthrax of the eyelid may be complicated by ectropion of the upper lid and corneal scarring with blindness.[50] Immunity probably is lifelong in most patients. Although second attacks of cutaneous anthrax have been recorded, they have not been confirmed serologically and usually are mild.[21] Fatality rates are high for systemic anthrax and range from 50 to 100 percent for gastrointestinal anthrax to virtually 100 percent for inhalation anthrax, but children who have survived these infections have no apparent sequelae.

PREVENTION

The only human anthrax vaccine licensed in the United States is anthrax vaccine adsorbed (AVA), marketed as BioThrax, which is prepared from cell-free filtrates of microaerophilic cultures of a toxigenic, nonencapsulated strain of *B. anthracis* V770-NP1-R. Each 0.5-mL dose contains proteins including the protective antigen and contains no dead or live bacteria.[14] The anthrax vaccine is licensed for use in persons 18 to 65 years of age who are at high risk for exposure. Preexposure vaccination is recommended for persons who perform certain types of laboratory work, including those who work with high concentrations or pure cultures of *B. anthracis* spores or with environmental samples associated with anthrax investigations and those who work in spore-contaminated areas or settings with exposure to aerosolized *B. anthracis* spores. Preexposure vaccination is recommended for persons involved in environmental investigations or remediation efforts and, as recommended by the U.S. Department of Defense, for military personnel. The preexposure vaccination schedule consists of five intramuscular doses administered at day 0, 4 weeks and 6, 12 and 18 months, followed by an annual booster to maintain immunity. AVA is not licensed for use in children and, in a pre-event setting, vaccination of children is not recommended.

The use of AVA in children is not contraindicated in a postevent setting that poses a high risk for exposure to aerosolized *B. anthracis* spores. Recommendations for postexposure use of AVA in children from birth to 17 years of age are made by public health authorities on an event-by-event basis.[4,14] Under the existing IND protocol, postexposure vaccination should be administered as a three-dose subcutaneous series at 0, 2, and 4 weeks postexposure in conjunction with a 60-day course of an appropriate antimicrobial agent.[11]

The recommended postexposure prophylaxis after exposure to aerosolized *B. anthracis* spores for children younger than 18 years of age is one of the following for 60 days: (1) ciprofloxacin 30 mg/kg per day orally divided every 12 hours, not to exceed 1000 mg every 24 hours; or (2) doxycycline 100 mg orally two times per day for children older than 8 years of age and larger than 45 kg or 4.4 mg/kg per day divided every 12 hours, not to exceed 200 mg per day, for children 8 years of age and younger and for those older than 8 years of age but weighing less than or equal to 45 kg. If susceptibility testing demonstrates an amoxicillin minimal inhibitory concentration less than or equal to 0.125, oral amoxicillin 80 mg/kg/day orally divided into three doses given every 8 hours with a maximal dose of 500 mg should be used to complete therapy.

Worldwide, anthrax is controlled through livestock immunization programs. Procedures to prevent the spread of anthrax in animals include disposal of contaminated carcasses by burning and annual vaccination of livestock in known enzootic areas. Novel approaches to the treatment of anthrax are under investigation and include nonantimicrobial drugs with activity against anthrax toxin components and evaluation of agents that inhibit binding or assembly of toxins.[5] All suspected or proven cases of anthrax should be reported to public health officials. Hospitalized patients should be kept under isolation until the lesions are bacteriologically sterile. Contaminated dressings and clothing must be burned or sterilized, and the patient's room must be disinfected to destroy spores.

CHAPTER 92

Bacillus cereus

Margot Anderson • Richard A. Oberhelman

Recognition of *Bacillus cereus* pathogenicity was delayed until clarification of the taxonomy of the genus *Bacillus* in the early 1950s. Multiple early reports of food poisoning and other infections, including gastroenteritis, bacteremia-septicemia, cellulitis, ear and eye infections, endocarditis, and urinary tract infections, that were attributed to *Bacillus subtilis* or to other *Bacillus* spp. probably were caused by *B. cereus.*[104] *B. cereus* can give rise to two distinct forms of foodborne diseases related to different toxins, the emetic and the diarrheal syndromes, and occasionally to localized and systemic disease.[43,66]

The diarrheal syndrome was recognized first by Hauge[51] in 1955 after four clinically similar outbreaks in Norway occurred. This common form of disease was related to a great variety of foods, such as meat and vegetable soup, poultry, pudding, sauce, pasta, cake, and milk. In 1974, Mortimer and McCann[82] described a vomiting syndrome associated with the consumption of fried

rice in Chinese restaurants. Despite widespread recognition in Europe, *B. cereus* outbreaks have been reported infrequently in the United States. The first documented outbreak in the United States occurred in 1970.[79]

BACTERIOLOGY

Members of the genus *Bacillus* are aerobic or facultative anaerobic, gram-positive or gram-variable, spore-forming rods. They are distributed widely in the environment because of the high resistance of their endospores to extreme conditions, including heat, cold, desiccation, salinity, and radiation.[34,93] Based on the high variability in guanine and cytosine content (32% to 69%), the debate ensues regarding the classification of *Bacillus* spp.[107]

B. cereus belongs to the group of gram-positive rods that produce central or terminal ellipsoid or cylindrical spores that do not distend the sporangia.[107] Studies of DNA-DNA hybridization and 16S and 23S ribosomal RNA (rRNA) sequencing and enzyme electrophoretic patterns have shown a close relationship among *B. cereus*, *Bacillus anthracis*, *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus weihenstephanensis*, and *Bacillus thuringiensis;* these organisms are so closely related that they all may be considered variants of *B. cereus* and are labeled the *B. cereus* group. Differentiating, particularly between *B. cereus* and the insect pathogen *B. thuringiensis*, sometimes is difficult in the diagnostic laboratory, and overlap occurs among clinical syndromes reported.[50,59] Polymerase chain reaction (PCR) technology has been used for identifying species.[18]

B. cereus sensu stricto is a flagellated, motile, gram-positive rod, typically 1 to 1.2 μm in diameter by 3 to 5 μm in length. The organism sporulates freely on many media under well-aerated conditions, but vegetative cells also can grow anaerobically. It is able to metabolize glucose, fructose, and sucrose but not pentose and other sugar alcohols. It produces acid from glucose but not from arabinose, xylose, or mannitol. Starch hydrolysis and catalase production are similar to those of the other members of the genus. The presence of lipid globules or protoplasts is a characteristic that it shares with *Bacillus megaterium*.[67] Colonies on blood agar are large, flat, granular, and slightly green-tinged. *B. cereus* is differentiated from *B. anthracis* by motility, hemolysis, lack of lysis by γ phage, penicillin resistance, and absence of a capsule in *B. cereus*.[34] Identifying morphologic differentiation with nonmotile *B. cereus* strains and *B. anthracis* strains that are occasionally weakly hemolytic may be difficult.

Growth and multiplication of vegetative cells occur in a temperature range of 10° to 50°C (50° to 122°F), with an optimum of 28° to 35°C (82.4° to 95°F). Variations in toxin levels found in certain foods also can be related to pH levels, sugar content, the presence of other lactic acid bacteria, and aeration.[98,99] Some strains responsible for milk spoilage can grow at temperatures of 5°C (41°F),[67,93] but few strains are able to produce toxin at temperatures less than 7°C (44.6°F).[93] Ribosomal DNA characterization and genotyping based on the major cold shock protein homologue cspA have defined the species, *Bacillus weihenstephanensis*, which can grow at 4° to 7°C (39.2° to 44.6°F) but not at 43°C (109.4°F).[69] These strains form a subgroup of *B. cereus* organisms described as psychrotolerant or psychrotropic, meaning they are able to grow at temperatures of 7°C (44.6°F) and less.[68,89,100] Spore formation allows some *B. cereus* strains to survive pasteurization and heating.[68] A crystalline cell surface protein layer or "S-layer" has been described as a determinant of cell hydrophobicity. S-layer–producing cells are hydrophilic and able to bind to human matrix proteins, and presence of the S-layer in some *B. cereus* strains is associated with resistance to phagocytosis and increased radiation resistance against γ irradiation.[66]

Serologic differentiation of *Bacillus* spp. is hampered by cross-reactive antigens and autoagglutination of spores caused by hydrophobic surface properties. Serologic typing based on the flagellar (H) antigen can be used during an outbreak to distinguish among strains and to determine the similarity of isolates obtained from humans with the strains isolated from suspect foods.[34] The serotype scheme is based on H antisera raised against prototype strains. In addition to serology, biochemical typing, plasmid analysis, and phage typing have proved useful epidemiologically.[2,67,83,96,113] A *B. cereus*–specific, repetitive, extragenic, palindromic sequence-based PCR analysis (Bc-Rep-PCR) appears to be a promising newer technique.[87,91] Pulsed-field gel electrophoresis (PFGE) has been less successful in differentiating among *B. cereus* group species.[121]

Diagnosis of the less common extraintestinal infection is made by isolation from normally sterile sites (blood or tissue) after overnight incubation on nutrient or blood agar; clinical specimens from normally nonsterile sites (feces, vomitus) and food or environmental samples require selective techniques. Polymyxin B is used as a selective agent, and the lecithinase reaction of the organism on egg yolk and its inability to catabolize mannitol permit presumptive identification to be made with a variety of media: mannitol–egg yolk–polymyxin B, Kim and Goepfert medium, and polymyxin B–pyruvate–egg yolk–mannitol with bromothymol blue or bromocresol purple.[34]

EPIDEMIOLOGY

B. cereus in the spore and vegetative form is a ubiquitous organism found in soil, water, vegetation, and food products, especially cereals, dairy products, dried foods, spices, meat products, and vegetables.[67] The emetic syndrome typically is associated with cooked rice, usually fried, from Chinese restaurants.[64,82] Saving portions of boiled rice at room temperature overnight until required for frying previously was a common practice. Refrigerating boiled rice makes the grains stick together, which is less convenient for frying. The spores of *B. cereus* survive cooking and are capable of germination and outgrowth.[44,46] The optimal temperature for growth in boiled rice is 30° to 37°C (86° to 98.6°F), although growth does occur during storage at 15° to 43°C (59° to 109.4°F).[44] Most samples of uncooked rice contain multiple serotypes of *B. cereus*, and little difference occurs in

the growth rate of the various serotypes in boiled rice at 22°C (71.6°F).[85]

Starchy dried foods other than rice, such as cereals, frequently are contaminated.[16] Tortillas can be contaminated with the water used in preparation and from the hands of producers.[22] Specific foods incriminated in outbreaks in the United States include Chinese food (accounting for 50% of reported outbreaks between 1973 and 1987), followed by Mexican food, beef, fruits, and vegetables. Other foods implicated, particularly in the enterotoxin syndrome, include beef stew, turkey loaf, barbecued pork, macaroni and cheese, potatoes, spaghetti and other pastas, dairy and dried milk products, and seafoods.* In a study of 96 milk and milk product samples collected from retail shops in Nairobi, Kenya, 57 percent of samples were contaminated with *B. cereus* and 81 percent of the bacterial isolates (38/47) produced nonhemolytic enterotoxins, including 6 of 43 pasteurized milk products (43%).[84] Among the factors thought to contribute to outbreaks, the most frequent were inadequate cold-holding temperatures, preparing foods a half-day or more before serving, contaminated equipment, and storage in a contaminated environment.[8,23] Outbreaks of *B. cereus* have been recognized widely in Europe but less often in the United States. In the Netherlands, *B. cereus* reportedly was the cause of 22.4 percent of foodborne disease outbreaks of known bacterial cause. Similarly, in Finland, it accounted for 11.9 percent of outbreaks. In most places, *B. cereus* is incriminated in 0.9 to 7 percent of outbreaks of food-related disease and 0.7 to 3 percent of cases.[67] In the United States, between 1998 and 2002, *B. cereus* was identified as the cause of 37/6647 (0.6%) foodborne outbreaks reported to the Centers for Disease Control and Prevention (CDC), with a total of 571 cases and no deaths recorded.[75] The location of the outbreak is known for 24 of these outbreaks, and most of these (15/24 [62.5%]) occurred in commercial food outlets, such as restaurants, delicatessens, or workplace cafeterias. In outbreaks for which the implicated source was known, cereal products were the most common vehicle.[75] The susceptibility of children to this pathogen is evident from the report of an outbreak involving two daycare centers[64] and other reports that included neonates, children, and adolescents.† Only a small fraction of outbreaks are reported to the CDC; small outbreaks of mild, brief illness are less likely to be reported. It is thought that 10^5 to 10^8 organisms per gram need to be ingested to cause the emetic syndrome and 10^5 to 10^7 cells or spores (total dose) ingested to cause the enterotoxin syndrome.[47]

For infections not related to food, groups at risk include neonates,[37,86] immunocompromised hosts,‡ patients with recent eye surgery or trauma, intravenous drug users,[27,108] and patients with intravascular devices or artificial prostheses.§ *B. cereus* has been known to contaminate a variety of unusual environmental niches, including alcohol prep pads,[33] steam-dried towels,[32] and unopened boxes of nonsterile nitrile gloves.[62] Studies in three populations in South Africa and London, including school-aged children, found the organism in 18 to 43 percent of fecal samples.[106] The organism can be part of the normal intestinal flora. *B. cereus* does not persist in the intestine after ingestion and so is not spread by the fecal-oral route.[41]

PATHOGENESIS

B. cereus produces an enormous range of extracellular metabolites, including peptides with antibiotic properties (biocerin, cerein, thiocillins), β-lactamases, hydrolases, nuclease, urease, and proteases.[104] Two groups of toxins, known as diarrheal enterotoxins and emetic toxins, are responsible for the clinical syndromes of food poisoning.[77,111] Some strains may be able to produce both toxins based on the evidence that culture filtrates derived from strains isolated from emetic poisoning occasionally are able to produce a positive rabbit ileal loop assay.[93]

Biologic activities of diarrheal enterotoxins can be shown in multiple different assay systems. Three enterotoxins are produced. Purification plus isolation of multiple toxic fractions with some, but not all, of these activities has caused confusion.[34,103] Evaluation of the toxic activity of whole-cell suspension, cell-free culture filtrates, and the purified enterotoxin complex classically has included the rabbit ileal loop fluid accumulation assay, vascular permeability in rabbit skin, dermonecrosis and intestinonecrosis, mouse lethality, cytotoxicity, and hemolysis.* Hemolytic *B. cereus* enterotoxin has been characterized as a complex termed *hemolysin BL*, composed of a binding component B (35 kDa) and two lytic components, L1 and L2 (36 kDa and 45 kDa, respectively)[9]; all three are needed for fluid accumulation in the rabbit ileal loop.[13] Other *B. cereus* enterotoxins, a nonhemolytic enterotoxin and cytotoxin K, also have been described.[17,66,74]

The emetic toxin cereulide is a heat-stable (126°C [258.8°F] for 90 minutes), ring-shaped peptide with a molecular weight of 1.2 kDa[78]; it is stable between pH 2.0 and 11.0 and is protease-resistant. In contrast to the diarrheal toxins, it is preformed in foods, so the presence of living organisms at the time of ingestion is not necessary to cause symptoms.[43,104] Rice culture filtrates derived from emetic syndrome–associated strains cause cytoplasmic vacuolation and swollen mitochondria in HEp-2 cells, characteristics suggestive of uncoupling of oxidative phosphorylation.[90] Emetic activity occurs through the serotonin 5-HT_3 receptor and stimulation of the vagus afferent nerve.[1]

Among the multiple other substances with relevant activity, two groups are associated with local infection.[105,110] Cereolysin, or hemolysin I, is a thiol-activated cytolysin. Phospholipase C–like or lecithinase-like substances, including a sphingomyelinase and two hydrolases with preference for phosphatidylcholine and phosphatidylinositol, also exist. These enzymes induce the release of lysosomal enzymes from neutrophils that probably are

involved in tissue damage, especially in wound and ocular infections.[34,119]

CLINICAL MANIFESTATIONS

Food Poisoning

Diarrheal Syndrome

The enterotoxins preformed in food or produced in vivo in the intestine after the ingestion of bacilli cause profuse, watery, nonbloody diarrhea accompanied by abdominal pain and cramps, nausea, and, occasionally, vomiting or low-grade fever.* The typical incubation period is 8 to 16 hours, and the clinical characteristics resemble the food poisoning of *Clostridium perfringens*. The interval between ingestion and the onset of symptoms reflects the time required for production of toxin in the gut. The symptoms resolve within approximately 12 to 24 hours but occasionally can last 2 days to 2 weeks.[42] The diarrhea (3 to 10 bowel movements per day) rarely leads to dehydration in healthy individuals. The most prevalent flagellar H serotypes are 1, 2, 6, 8, 10, 12, and 19. Serotyping is available at research laboratories.[16,31,72,106]

Emetic Syndrome

The usual illness is characterized by a rapid onset (within 1 to 5 hours after the ingestion of contaminated food) of nausea, vomiting, and malaise, occasionally followed by diarrhea hours later.[82] Infrequently, the diarrhea is reported to last several days.[114] The short incubation reflects the ingestion of preformed emetic toxin.

Extraintestinal Infections

Eye Infection

Keratitis, conjunctivitis, endophthalmitis, and panophthalmitis can be produced by *B. cereus*. Endophthalmitis that develops after the occurrence of penetrating wounds is caused by this organism in 27 to 46 percent of cases.[29,112] A history of soil contamination or the presence of a metal foreign body should raise clinical suspicion. Less frequently, corneal ulcers and surgical procedures are predisposing factors.[52,112] Exogenous endophthalmitis usually progresses rapidly, with deterioration of vision occurring in less than 48 hours. Severe pain is accompanied by chemosis, periorbital swelling, proptosis, and pus in the anterior chamber. The classic lesion is a corneal ring abscess, similar to that produced by *Pseudomonas* and *Proteus* spp. Endogenous cases may have subretinal exudation, retinal hemorrhage, and perivasculitis. Associated systemic symptoms are not unusual manifestations.[27] The outcome is poor, with almost half of patients left with visual acuity no better than simple light perception.[112] Many patients require enucleation. Endogenous ophthalmitis is associated with the use of illicit intravenous drugs or transfusion of contaminated blood products and subsequent bacteremic seeding of one eye.[27,96,102,112]

The pathogenesis of *B. cereus* on ocular tissue has been linked to the lecithinase activity of phospholipase C. A toxin fraction, hemolysin BL, which is formed by three separate components, produces similar destruction of retinal tissue in vitro and in animal experiments.[12] Its relationship with the diarrheal enterotoxin is unclear.[11]

Wound and Soft Tissue Infections

Wound infections of variable severity related to trauma, burns, or postsurgical complications occasionally are reported.[105,108,110,117] Because *Bacillus* is a common environmental contaminant, proof of the relevance of a *B. cereus* isolate is clearer if the organism is obtained from deep tissue in heavy pure growth. Severe infections in individuals involved in motor vehicle accidents can be complicated by necrotizing fasciitis and require extensive débridement.[117] Superficial, benignly infected wounds are common findings in the tropics.[35] Immunosuppressed patients may contract a severe gas gangrene–like infection with myonecrosis similar to disease caused by *Clostridium* spp.,[78] requiring amputation,[49] or a less severe primary cutaneous infection manifested by vesicles, pustules, or cellulitis.[53]

Skeletal Infections

Cases of chronic osteomyelitis occur rarely and result from accidental or surgical trauma. Radical débridement and antibiotic treatment are required.[96] Because *B. cereus* can be found as a copathogen with other, more frequent pathogenic bacteria, resolution of symptoms is delayed until eradication of the organism.[94] Acute osteomyelitis may occur in drug users.[96,102]

Bacteremia and Septicemia

Bacteremia occurs with indwelling catheters and other foreign bodies, contaminated intravenous drugs (e.g., heroin), and blood products, particularly platelets.[19,36,120] Immunosuppression and impaired neutrophil killing, such as occur in individuals with neutropenia secondary to malignancy or chemotherapy and in neonates with immaturity of the immune system, are major contributors to morbidity in systemic *B. cereus* infection.* Disseminated intravascular coagulation, multiorgan failure, and a fulminant course may occur in neonates and compromised hosts. Intestinal perforation with abdominal infection in neonates also has been described.[45] Outbreaks of sepsis in newborn nurseries have been linked to contaminated ventilation balloon devices.[115] Endocarditis is an infrequent complication of bacteremia that usually occurs in intravenous drug users or individuals with a long-term intravascular device.[96,102] Vegetations can form over mechanical prosthetic valves or pacemaker wires, requiring their replacement.[96,97] Morbidity and mortality rates are high in patients with valvular heart disease. Fatal serosanguineous pericarditis in a patient undergoing hemodialysis has been reported.[38]

*References 5, 20, 56, 57, 86, 88.

Pneumonia

Primary pulmonary disease rarely has been recorded. Underlying predisposing conditions include leukemia, alcohol abuse, chronic hepatitis, and steroid use.[14,36,56,96] Multiorgan disease in premature neonates with necrotizing pneumonia usually is fatal.[63] Outbreaks of *B. cereus* pneumonia in neonates have been linked to contaminated ventilators.[48] Blood culture is positive in 75 percent of cases, followed by pleural fluid and sputum culture in 40 to 60 percent.[14] The pleural space may become contaminated with *B. cereus* by mishandling of the thoracic drainage system in patients with other causes of pleuritis.[58]

A dramatic pulmonary syndrome similar to that of inhalational anthrax has been seen in adults (all metal workers) with *B. cereus* infection. The organisms in these cases possessed some *B. anthracis* toxin genes while being clearly phenotypically *B. cereus*.[3,54,55]

Infection of the Central Nervous System

Premature neonates are susceptible to meningeal seeding by dissemination of intravascular infection related to catheters.[86] As in patients with other serious infections, patients who are immunosuppressed are at higher risk.[56] The cerebrospinal fluid in *B. cereus* meningitis is purulent, with white blood cell counts of more than 1000/mm^3, a predominance of polymorphonuclear leukocytes, and moderate increments in protein content. Gram stain is positive in 70 percent of cases. Multiple brain abscesses may result from hematogenous spread in patients with leukemia.[56,60] Sequelae include hydrocephalus and brain damage. Often, these infections are fatal.

Intracranial shunts and penetrating surgical or traumatic cranial wounds expose the central nervous system to environmental *B. cereus*.[37,94] Spinal anesthesia[36] was associated with *Bacillus* infection in the past. Contamination in the operating room through the linen is a potential source.[6,7] These infections are typically more benign.

Liver Failure

Fulminant hepatitis and rhabdomyolysis have been associated with the emetic toxin. The toxin inhibits hepatic mitochondrial fatty acid oxidation. Liver changes include fatty infiltrates and midzonal necrosis.[76]

Pseudoinfections

Pseudoepidemics with *B. cereus* are a challenge for the clinical microbiologist.[80] Because these spore formers are so hardy, they are common laboratory contaminants. *Bacillus* spp. isolated from a single clinical specimen usually should be considered a contaminant, although their pathogenic potential is well known.* Pseudoinfections have been associated with contaminated blood culture media, syringes, blood culture analyzers, and fiberoptic bronchoscopes.[28] Colonization of umbilical cord stumps and eye surfaces by contaminated linens may cause pseudo-outbreaks in nurseries.[118]

*References 28, 36, 57, 88, 96, 102, 105, 110.

COMPLICATIONS

Death rarely ever results from the food-poisoning syndromes. Rapidly spreading wound infections may require amputation of extremities,[46] and ocular infections can lead to loss of vision with or without enucleation.[52,112,119] The risk for death in patients with septicemia, endocarditis, and meningitis is related to the underlying condition and severity of the disease.[5,53,81,86,97]

DIAGNOSIS

The laboratory finding of *B. cereus* in a foodstuff without quantitative cultures and without epidemiologic data is insufficient to establish its role in an outbreak.[114] In practice, appropriate specimens often either are unavailable or are submitted long after the incident, rendering their microbiologic significance questionable. During analysis of foods not involved in foodborne illness, the bacteria may be found in counts of 10^1 to 10^6 organisms per gram.[15,16,22,44,85,98] Diagnosis of the diarrheal form of *B. cereus* food poisoning is supported by the isolation of 10^5 or more organisms per gram from epidemiologically incriminated food.[81] The levels of *B. cereus* found in the implicated foods usually are in the range of 5×10^5 to 9.5×10^8 colony-forming units per gram. With the exception of milk, the products rarely appear to be spoiled, despite the bacteria's high density. Isolation of more than 10^5 organisms per gram in feces during an acute attack provides supportive evidence for the presumed diagnosis and confirms the association if the same serotype is isolated from incriminated food.

The organisms that produce emetic toxin are present in concentrations of 1×10^3 to 5×10^{10} colony-forming units per gram. Reheating may decrease or eliminate the organisms and leave the toxin intact, but render isolation of the organism difficult to accomplish.[34,114] Accurate PCR assays for the presence of the emetic toxin–producing *B. cereus* have been developed and can be performed on food samples.[39,65]

Commercial immunoassay kits (reversed passive latex agglutination test, enzyme-linked immunosorbent assay, and microslide immunodiffusion assay) are available for the detection of *B. cereus* diarrheal toxin. The kits may detect a variety of proteins, however.[10,12,30] Experimental techniques based on the detection of genes for phospholipase C and sphingomyelinase by PCR have been developed for the identification of *B. cereus* in food products.[78]

The relevance of clinical isolates in extraintestinal syndromes can be assessed by the degree of growth (heavy vs. scanty), the number of occasions that growth was obtained, the source of the material cultured, and predisposing or underlying conditions.[105] For suspected endophthalmitis, aqueous and vitreous samples should be obtained.[29]

TREATMENT

During a mild, self-limited attack of food poisoning, patients require only supportive therapy. Usually, oral fluid and electrolyte replacement is adequate (Table 92-1).[42]

TABLE 92-1 **Management and Complications Associated with *Bacillus Cereus* Infections**

Condition	Management	Complications
Food poisoning	Supportive measures; hydration	Usually none; liver failure rarely reported
Ocular	Systemic, topical, intravitreal antibiotics: vancomycin and/or ciprofloxacin; surgical—early vitrectomy[21]	Severe decreased visual acuity, blindness, enucleation
Septicemia	Removal of IV device, foreign body; IV antibiotics (according to sensitivity): vancomycin	Localization of infection: endophthalmitis, endocarditis, meningitis; death
Pneumonia/pleuritis	IV antibiotics; drainage of pleural space; resection of necrotic tissue	Death
Meningitis	IV antibiotics; removal of infected intracranial shunts or cerebrospinal fluid reservoirs	Hydrocephalus, brain damage, death
Wound/subcutaneous infection	IV antibiotics; surgical débridement	Amputation, death

IV, Intravenous.

No antibiotic therapy is required except in cases of nongastrointestinal infection. The production of three β-lactamases by most of the organisms renders penicillin derivatives, including third-generation cephalosporins, ineffective against *B. cereus*. Most strains are susceptible to chloramphenicol, vancomycin, clindamycin, aminoglycosides, erythromycin, tetracycline, imipenem, and ciprofloxacin.[5,25,105,110,116] Definitive antibiotic therapy should be based on the antibiogram susceptibility, but initial empirical therapy with clindamycin or vancomycin, with or without an aminoglycoside, is appropriate, pending susceptibility data.* Ciprofloxacin has also been reported to be useful in the treatment of recurrent pneumonia and bacteremia[40] and may have advantages in the penetration of respiratory and eye secretions.[70] Immediate empirical coverage for *B. cereus* is indicated for endophthalmitis in groups at risk. Vancomycin and ciprofloxacin administered intravitreally are the best options.[21] In cases of penetrating trauma, early vitrectomy should be considered.[29,112]

Surgical débridement of necrotic tissue, drainage of closed-space infections, and prompt removal of foreign bodies and indwelling catheters are important aspects of successful therapy.[14,26,92] Some bacteremic patients may be cured by removal of the intravenous catheter only.[96]

PREVENTION AND CONTROL

Low-level contamination in food products is difficult to avoid, but proper food handling should diminish the proliferation of bacilli.[93] Practical precautions for handling cereals and rice include not preparing large quantities at a single time and maintaining the food at a hot temperature (>63° C [96.8° F]) or cooling it quickly. The food must not be stored under warm conditions, especially in the range of 15° to 50° C (59° to 122° F).[16,44]

CHAPTER 93

Arcanobacterium haemolyticum

Natascha Ching

Arcanobacterium haemolyticum is a pleomorphic gram-positive coryneform rod that causes pharyngitis and exanthem in children and young adults.[18,40,44,50]

HISTORY

This diphtheroid was first noted by MacLean and colleagues[44] in association with exudative pharyngitis in American servicemen in the South Pacific during World War II. The organism originally was named *Corynebacterium haemolyticum* but was reclassified in 1986 as *A. haemolyticum* on the basis of phenetic, peptidoglycan, fatty acid, menaquinone, and DNA data.[16-18] The association between infection with *A. haemolyticum* and pharyngitis was observed repeatedly over the years, but a cause-and-effect relationship between the organism and illness has been established only relatively recently.[11,44,50]

THE ORGANISM

Microbiology[18,20,26,70,73]

A. haemolyticum is a gram-positive to gram-variable pleomorphic rod. Its laboratory characteristics are presented in Table 93-1. The organism grows best at 37° C (98.6° F) on a blood- or serum-enriched medium with the addition of 5 percent carbon dioxide. Alternatively, it grows well anaerobically. On rabbit or human blood agar, colonies are pinpoint (0.5 mm) at 24 hours; they increase to 1 to 1.5 mm after 48 hours. At this time, a unique black opaque dot is noted in the center of the colony, and this dot remains on the agar when the colony is scraped away.

At 24 hours, a 1-mm zone of hemolysis develops around colonies grown on human or rabbit blood agar. The hemolytic zone increases to 3 to 5 mm by 48 hours. Both growth and red cell hemolysis are minimal on horse and sheep blood agar. Because throat cultures usually are performed on sheep blood agar plates, the hemolytic activity of *A. haemolyticum* may be missed.

Colonies of *A. haemolyticum* can be of either the smooth or rough biotypes on horse blood agar.[10] These biotypes also differ in their hemolysis and biochemical properties. Smooth colonies predominate in wound infections and frequently use sucrose and trehalose, are β-hemolytic, and lack β-glucuronidase. Rough colonies are found almost exclusively in the respiratory tract and do not use sucrose and trehalose, are nonhemolytic, and are β-glucuronidase–positive.

A. haemolyticum resembles *Actinomyces pyogenes* (formerly *Corynebacterium pyogenes*), a common cause of bovine mastitis and a rare cause of skin ulcers in children.[36] These organisms can be differentiated by several means. *A. pyogenes* is able to hydrolyze gelatin and ferment xylose. In addition, *A. haemolyticum* has a positive reverse Christie, Atkins, and Munch-Petersen (CAMP) test in that it inhibits the β-hemolysis of *Staphylococcus aureus*, whereas *A. pyogenes* shows slight enhancement of β-hemolysis.[25] The poor growth of *A. haemolyticum* on tellurite medium and lack of catalase help distinguish it from *Corynebacterium diphtheriae*, which also causes pharyngitis.[31,38,40]

Toxin Production

A. haemolyticum liberates three toxins: phospholipase D (PLD), a hemolysin, and neuraminidase.[18] PLD is a dermonecrotic toxin that after intradermal inoculation in rabbits and guinea pigs causes local hemorrhagic necrosis; injection of PLD also is lethal in rabbits.[58] The PLD gene of *A. haemolyticum* has a high degree of homology to that of *Corynebacterium pseudotuberculosis*.[19,47] PLD has been shown to be involved in the virulence of *C. pseudotuberculosis;* PLD mutants are less pathogenic in experimental infections in goats.[46] The PLD of *C. pseudotuberculosis* is similar biochemically and shares some biologic activity with the PLD that is found in brown recluse spider venom and that plays a role in the venom's toxicity.[6,40] *A. haemolyticum* carries a gene similar to the gene encoding the erythrogenic toxin of *Streptococcus pyogenes*.[18]

Antimicrobial Susceptibility

Almost all *A. haemolyticum* strains are highly susceptible to erythromycin (minimal inhibitory concentration <0.06 μg/mL). However, erythromycin is not bactericidal.[9,44,70] Carlson and colleagues[12] reported an *A. haemolyticum* isolate from a diabetic foot ulcer that was exceptionally resistant to macrolides, clindamycin, tetracycline, and ofloxacin. Waagner[70] noted that of 100 pharyngeal isolates, all were inhibited by concentrations of 0.25 μg/mL or less of penicillin G and by 1 μg/mL of penicillin V. However, tolerance to penicillin has been observed.[44,55] In one study, the minimal bactericidal concentration–minimal inhibitory concentration ratio varied from 1:1 to 1:8.[44] In addition to being susceptible to penicillin and erythromycin, *A. haemolyticum* also is susceptible to other β-lactams, clindamycin, chloramphenicol, azithromycin, vancomycin, ciprofloxacin,

TABLE 93-1 **Identification Characteristics of *Arcanobacterium Haemolyticum***

Test or Characteristic	Finding
Catalase	Negative
β-Hemolysis	Positive (a narrow zone of slight hemolysis after 48 hr on sheep blood)
Nitrate reduction	Negative
Pigment production	White or gray
Urease	Negative
Gelatin hydrolysis	Negative
Motility	Negative
Esculin hydrolysis	Negative
Carbohydrate usage	
Glucose	Positive
Maltose	Positive
Sucrose	Positive (requires rabbit serum for growth in peptone water)
Mannitol	Negative
Xylose	Negative

Data from Collins MD, Cummins CS. Genus *Corynebacterium*. In: Sneath PHA, Main NS, Sharpe ME, et al, editors. Bergey's manual of systemic bacteriology. Vol. 2. Baltimore, Md, Williams & Wilkins; 1986, p. 266-76.

tetracyclines, and rifampin; most strains are resistant to sulfonamides and trimethoprim-sulfamethoxazole.[9,12,70]

Carlson[8] compared the E test and agar dilution methods for susceptibility testing of 12 antimicrobial agents in 70 *A. haemolyticum* isolates. E test and agar dilution method results for benzylpenicillin, clindamycin, erythromycin, imipenem, levofloxacin, rifampin, and vancomycin were in 100 percent agreement. Tetracycline, ciprofloxacin and ofloxacin were in agreement between 97 and 99 percent of the time, but a lower percentage of agreement was found for cefotaxime and cefuroxime, at 93 and 84 percent, respectively. The author reinforces the concept that because there are no universal standards for the organism in regard to susceptible, intermediate, or resistant categories, results should be interpreted with caution for clinical care. Almuzara and associates[1] also evaluated the susceptibility of 19 strains of *A. haemolyticum* according to National Committee for Clinical and Laboratory Standards (now the Clinical and Laboratory Standards Institute [CLSI]) interpretative standards for aerobic organisms. The majority of isolates were susceptible to penicillin, cephalosporins, clindamycin, ciprofloxacin, vancomycin, and macrolides (erythromycin and azithromycin). However, only 68 percent of isolates were found to be sensitive to tetracycline.

Recommendations for antimicrobial susceptibility testing of *Arcanobacterium* are provided in CLSI document M45 entitled "Methods for Antimicrobial Dilution and Disk Susceptibility Testing of Infrequently Isolated or Fastidious Bacteria." Table 5 is for *Corynebacterium* spp. and coryneforms and also applies to *Arcanobacterium* spp. The recommended MIC method for testing *Arcanobacterium* spp. uses broth microdilution with cation-adjusted Mueller-Hinton broth (CAMHB) supplemented with 2.5 to 5 percent lysed horse blood (CAMHB-LHB); there is currently no disk diffusion method recommended.[15] This method involves testing in cation-adjusted Mueller-Hinton broth supplemented with lysed horse blood (2.5% to 5% v/v). Some investigators have used agar dilution or E test satisfactorily.[8]

A vancomycin-resistant *A. haemolyticum* isolated from stool during an outbreak of vancomycin-resistant enterococci has been described. It contained the *vanA* gene primarily found in *Enterococcus faecium*.[59] Two other case reports have described organisms resistant to ciprofloxacin[68] and tetracycline.[39]

EPIDEMIOLOGY

Although similar organisms are common causes of infection in animals, humans appear to be the primary host of *A. haemolyticum*.[60,70] The organism is isolated primarily from throat specimens in patients with pharyngitis,[44,50,70] although it also may be a commensal of human skin.[43] It likewise may be a commensal in the throat but often is overlooked because laboratories frequently do not differentiate diphtheroids, which are considered "normal flora." In addition, because *A. haemolyticum* often is found in polymicrobial respiratory tract infections with classic respiratory pathogens, including *S. pyogenes*, it sometimes is missed when these more classic pathogens are identified.[40]

Although no definitive data are available, spread from person to person is assumed to be from the throat discharge of an infected person to the throat of a susceptible host. Transmission could occur directly or indirectly by fomites. Secondary cases in families indicate that spread is from person to person rather than from an environmental source.[23,50]

In an 8-year study, the organism was found to be isolated from throat specimens in each year, with isolation rates varying from 0.2 to 0.7 percent.[50] The peak age for contracting illness caused by *A. haemolyticum* is during the second decade of life; in contrast, the peak age for developing pharyngitis caused by *S. pyogenes* is during the first decade of life.[23,44,50] In two studies, illnesses occurred more commonly in females than in males.[23,50] In a review of *A. haemolyticum* systemic and deep-seated infections, a preponderance of males over females was found in adolescents with no risk factors for development of invasive disease.[64] No seasonal prevalence has been reported.

Screening throat cultures for pharyngotonsillitis in northern Israel was performed in 518 throat cultures in patients aged 1 to 90 years.[14] Only one culture was positive (0.2%) for *A. haemolyticum* in contrast to 26 percent recovery of group A *Streptococcus*. However, the one case was in a 9-year-old patient and only 58.7 percent of patients were 1 to 18 years old, the more common age of isolation for this organism.

PATHOGENESIS AND PATHOLOGY

Few data are available regarding pathogenesis and pathology. The dermonecrotic toxin probably plays a role in pharyngitis. Skin biopsy specimens were taken from the

exanthem in two patients, and both showed only a mild lymphohistiocytic perivascular infiltrate.[50] Cultures of both samples were negative, and no IgG, IgA, or IgM deposition was noted. These findings suggest that the rash may be toxin-mediated, like the rash in group A streptococcal infections.

A. haemolyticum has been found to persist intracellularly,[56] which might account for failure of penicillin treatment in some cases.

In one study, 5/42 patients were found to have apparent dual infections with Epstein-Barr virus and *A. haemolyticum*.[44] The authors of this study suggested that immune suppression by the virus contributes to a more marked effect of the bacterial infection in the throat.

With regard to the immune response to *A. haemolyticum*, paired acute and convalescent sera showed the development of a humoral response to four distinct cell wall–associated proteins on Western blot analysis in 7/8 patients with culture-confirmed infection.[54]

CLINICAL MANIFESTATIONS

Pharyngitis

Pharyngitis* is the most common finding in *A. haemolyticum* infection. Signs and symptoms associated with pharyngitis are presented in Table 93-2. The illness is indistinguishable from that caused by group A streptococci; frequently, it resembles Epstein-Barr virus infectious mononucleosis. Several patients with typical infectious mononucleosis had laboratory evidence of infection with both Epstein-Barr virus and *A. haemolyticum*.[28,29,44] Peritonsillar abscess caused by *A. haemolyticum* has been reported on several occasions.[4,38,41,49] The most common exanthem is scarlatiniform, which has an onset 1 to 4 days after the beginning of pharyngeal symptoms. The rash is most prominent on the extensor surfaces of the arms and legs (Fig. 93-1). Circumoral pallor, which is seen with group A streptococcal scarlet fever, does not seem to occur with *A. haemolyticum* infection. The rash may progress to involve the chest and back; it usually spares the palms, soles, and face, and it rarely involves the abdomen and buttocks.

The rash frequently is pruritic and may be urticarial. Erythema multiforme has been described.[3] Gaston and Zurowski[27] reported a 20-year-old man who had, in addition to pharyngitis, a rash involving mainly his hands and feet. His feet were swollen, and on the soles were erythematous macules, petechiae, and vesicles. His palms were tender, and 2- to 4-mm erythematous macular lesions that contained small central vesicles were present. Recently, Mehta[48] reported a 19-year-old woman who presented with pharyngitis and a pruritic rash on her arms and legs 4 days before evaluation. Physical examination revealed an erythematous, urticarial rash with large and small annular rings over the whole body with confluence on the upper thighs and smaller lesions groups on distal dorsal parts of the hands and feet.

Carlson and associates[13] also reported a 19-year-old man who presented with a 2-day history of a pruritic exanthem on the upper back and chest that spread centrifugally. The patient had pharyngitis that worsened to exudative tonsillitis, and a throat culture was positive for *A. haemolyticum*. He also had swollen fingers and worsening erythematous maculopapular exanthem over his trunk and proximal extremities. Interestingly, Pastia's lines were observed on the third day. Two weeks after antimicrobial treatment and discharge, a mild late desquamation was noted on the palms and around fingernails.

The duration of the exanthem has not been described adequately in the literature. In one study, exanthem was

*References 3, 11, 23, 27, 29, 31, 35, 43, 44, 50, 52, 53, 61-63, 69, 70.

TABLE 93-2 **Signs and Symptoms in Children, Adolescents, and Young Adults with *Arcanobacterium Haemolyticum* Infection**

Symptoms	Frequency (%)
Sore throat	100
Rash	40-70
Pruritus	50
Fever	40-75
Hoarseness	60
Cough (nonproductive)	40-60
Vomiting	30
Signs	
Pharyngitis or tonsillitis	100
Exudative	50-70
Palatal petechiae	30
Glossitis	25
Cervical lymphadenitis	40-75
Rash	40-70
Scarlatiniform	50
Urticarial	5
Maculopapular	25

Data from references 23, 32, 41, 46, 64.

FIGURE 93-1 ■ An erythematous maculopapular discrete and confluent rash on the thigh and arm of a 16-year-old girl with pharyngitis and *Arcanobacterium haemolyticum* isolated from her throat. (From Mackenzie A, Fuite LA, Chan FTH, et al. Incidence and pathogenicity of *Arcanobacterium haemolyticum* during a 2-year study in Ottawa. Clin Infect Dis 1995;**21**:177-81.)

noted to persist for longer than 2 days in 69 percent of patients.[46]

On occasion, *A. haemolyticum* infection has been manifested as a grayish-white pharyngeal pseudomembrane that has been confused with diphtheria.[3,31,34,38] *C. diphtheriae* and *A. haemolyticum* are diphtheroids that cannot be distinguished on Gram stain but can be differentiated by their biochemical properties.

Skin Infections

In the initial report of infections with *A. haemolyticum* in 1946, MacLean and associates[44] noted both pharyngitis in U.S. servicemen and skin infections in the native populations of the South Pacific Islands. Cutaneous infections have been observed mainly in tropical countries.[70] The most common manifestations are ulcerative lesions that resemble ecthyma. Cellulitis, wound infections, and paronychia all have been noted.* In wound infections, mixed infections with *A. haemolyticum* and other organisms are common findings.

Tan and colleagues[66] report five cases of *A. haemolyticum* bacteremia associated with soft tissue infections in adults. These patients had a history of soft tissue infections; two elderly bedridden patients had decubitus ulcers, and three diabetic patients had foot ulcers with extensive involvement that required surgical débridement. Four patients also had *A. haemolyticum* isolated from the suspected soft tissue focus of infection. A 3-year retrospective review of clinical samples over the same period as the five reported cases revealed 25 isolates of *A. haemolyticum*. Isolates from wound infections or cellulitis were found in 96 percent of cases; 20 percent of those patients also had bacteremia. Cultures from nonsterile sites were often polymicrobial, but the authors report *A. haemolyticum* was usually the predominant isolate.

Malini and colleagues[45] report three individuals with soft tissue infections with mixed infections with *A. haemolyticum* and β-hemolytic streptococci group G in a patient with cellulitis, β-hemolytic streptococci group A in postoperative wound infection, and *Proteus vulgaris* in a diabetic patient with chronic osteomyelitis. Each of these patients responded to erythromycin alone or in combination with penicillin with ciprofloxacin therapy. *A. haemolyticum* may have a synergistic role in tissue damage in these mixed soft tissue infections.

Other Manifestations

Isolated instances of septicemia, brain abscess, meningitis, meningoencephalitis, orbital cellulitis, endocarditis, osteomyelitis, septic arthritis, deep soft tissue infections, pleural empyema, cavitary pneumonia, pyothorax, Lemierre's disease, and sinusitis have been attributed to *A. haemolyticum* infection.† Most of these serious infections occurred in adults and frequently were associated with underlying conditions such as diabetes, a malignancy, or intravenous drug use. In a 1998 review of systemic and deep-seated infections caused by *A. haemolyticum*, Skov and associates[64] identified two groups of patients. The first group was composed of middle-aged to elderly adults who were immunocompromised or had other known risk factors for development of serious infectious disease. The second group consisted of preteens to young adults with no known risk factors except for one individual receiving steroid treatment for Epstein-Barr virus infection. Therriault and colleagues[67] report a case of sepsis with *A. haemolyticum* bacteremia, cavitary pneumonia, and pyomyositis that resolved with combination therapy of penicillin and azithromycin in an 18-year-old man with only a past history of mild asthma. Cultures were positive for *A. haemolyticum* from blood, bronchoalveolar fluid, and surface and surgical cultures from a lower extremity abscess.

A pyothorax with multiloculated hydropneumothorax has been reported in a 19-year-old man in India with no history of pharyngitis.[57] Pure growth of *A. haemolyticum* was obtained from the thoracocentesis. Treatment consisted of a therapeutic thoracocentesis and continued chest tube drainage for 1 month. Ceftriaxone and metronidazole were given for a month, and the patient had clinical and radiologic resolution.

A brain abscess was documented in an 18-year-old man in Venezuela with history of multiple periodontal problems, with periodontitis, dental caries, and multiple tooth extractions.[68] The patient had headache, vomiting, and neurologic deficits in the left extremities. Computed tomography (CT) of the brain revealed a left-sided hypodense frontoparietal lesion with cystic, contrast ring enhancement, edema, and midline mass effect. With worsening neurologic status, a craniotomy was performed and aspiration of purulent material from the encapsulated mass revealed positive cultures with pure *A. haemolyticum* growth. Therapy consisted of ceftriaxone and metronidazole for 1 week and was switched after susceptibility testing to penicillin for 3 weeks. Limjoco-Antonio and colleagues[39] report a 9-year-old girl with a swollen right eye after blunt trauma. She had ethmoid and maxillary sinusitis and orbital cellulitis, which required surgical drainage, débridement of subperiosteal abscess, and a second procedure with external ethmoidectomy and endoscopic sinus surgery. Cultures from the ethmoid sinus grew *A. haemolyticum*, and she was treated with ceftriaxone and clindamycin.

Infective endocarditis caused by *A. haemolyticum* has been reported in a 21-year-old woman with history of congenital heart disease repaired as a child; she was on lifelong warfarin anticoagulation therapy.[75] This patient had fever, lethargy, and a swollen, painful left calf. A transthoracic echocardiogram raised concerns of vegetations on the mitral valve and ventricular septal defect patch. As a result of the occurrence of a grand mal seizure, a large right frontal parenchymal hematoma with smaller frontal abscesses was found on CT of the head. She required a frontal craniotomy for evacuation of the hematoma. Blood culture revealed *A. haemolyticum* in 1/12 sets, which was confirmed by 16S rRNA gene sequencing. Antimicrobial therapy consisted of ceftriaxone with addition of gentamicin, for 6 weeks total therapy.

*References 7, 22, 23, 37, 49, 51, 70, 74.
†References 2, 5, 21, 25, 28, 29, 30, 32, 33, 39, 42, 57, 64, 66, 67, 69, 70-72, 75-77.

The initial therapy of vancomycin and metronidazole was given for only 2 weeks after identification of *A. haemolyticum*.

Fernandez-Suárez and colleagues[24] report *A. haemolyticum* has been associated with Lemierre's disease and septicemia in a 23-year-old male who presented with acute pharyngotonsillitis. The patient underwent cervical contrast-enhanced CT, which revealed complete thrombosis of the left internal jugular vein. Enoxaparin was initiated, with a transition to another anticoagulant (acenocoumarol) for 3 months as an outpatient. Antimicrobial therapy consisted initially of high-dose amoxicillin-clavulanate and metronidazole, but was changed to imipenem-cilastatin and metronidazole when right basal pneumonia was diagnosed along with bilateral pleural effusions. The patient completed 7 days of intravenous antibiotics and was transitioned to clindamycin as an outpatient for 10 days. All three blood cultures were positive for *A. haemolyticum*.

Lemierre's disease with coinfection of *A. haemolyticum* and *Fusobacterium necrophorum* bacteremia was reported by Younus and colleagues.[77] A 21-year-old man presented with fever, sore throat, tenderness along the border of his left sternocleidomastoid muscle, crackles, a blanching maculopapular rash, sepsis, and worsening pulmonary symptoms. The initial blood culture had *F. necrophorum*, and repeat blood cultures from day of admission had *A. haemolyticum* before antimicrobial therapy. CT of the chest revealed multiple nodular densities in the lungs, with evidence of central necrosis in one area. Therapy consisted of anticoagulation with heparin, initial antimicrobial therapy of gatifloxacin and metronidazole, which was switched to vancomycin and piperacillin-tazobactam for 2 weeks, followed by an oral course of amoxicillin-clavulanate for 3 months, but no surgical intervention was needed.

Differential Diagnosis

Pharyngitis caused by *A. haemolyticum* must be differentiated from all other causes of pharyngitis (see Chapter 9). Of particular importance is distinguishing *A. haemolyticum* pharyngitis from *S. pyogenes* pharyngitis. Such differentiation can be achieved with certainty only by specific culture. In *A. haemolyticum* infection, the rapid group A streptococcal antigen tests will be negative, as will the usual group A streptococcal culture. These negative tests in specimens from adolescents should suggest strongly the possibility of *A. haemolyticum* pharyngitis.

When exanthem occurs, the confusion with illness caused by *S. pyogenes* is more pronounced. In many cases, the rash in patients infected with *A. haemolyticum* is scarlatiniform. However, the lack of typical circumoral pallor and a tendency for more discrete lesions in *A. haemolyticum* infection occasionally may help in making the clinical diagnosis.

Other common causes of pharyngitis and exanthem in adolescents and young adults are *Mycoplasma pneumoniae* and Epstein-Barr virus infections. As noted by Mackenzie and colleagues,[43] *A. haemolyticum* and Epstein-Barr virus coinfections are not uncommon occurrences. Concurrent *M. pneumoniae* pneumonia and *A. haemolyticum* empyema and bacteremia have been reported in a previously healthy 20-year-old man.[65]

Cutaneous infections, including subacute ulcerations, wound infections, cellulitis, and paronychia caused by *A. haemolyticum*, must be differentiated from those caused by other organisms, such as staphylococci and streptococci.

SPECIFIC DIAGNOSIS

A specific diagnosis is made by culturing *A. haemolyticum* from the pharynx, a skin lesion, or a sterile body site in invasive infections. Culturing is done best with rabbit or human blood agar and the addition of 5 percent carbon dioxide.[18,20,70,73] An important note is that horse or sheep blood agar, which generally is used for culture of *S. pyogenes*, is not satisfactory for the growth and identification of *A. haemolyticum*. Using biochemical identification systems, such as the API (RAPID) Coryne strip or the Biolog system, can help differentiate *A. haemolyticum* from other coryneform bacteria. The Biolog system can make the identification in 4 hours.[26]

TREATMENT

A. haemolyticum is highly susceptible to numerous antibiotics.[9,10,44,53,70] Although no specific treatment studies have been performed, the experience in several large studies suggests that both penicillin and erythromycin are effective.[9,35,44,50] Clinical failure with penicillin has been noted.[3,52,70] Therefore, erythromycin has been suggested for first-line therapy for certain indications, such as *A. haemolyticum* tonsillitis.[12] Carlson and coworkers[12] suggest using either a broad-spectrum β-lactam antibiotic, clindamycin, or macrolides for serious systemic *A. haemolyticum* infection, although these authors do acknowledge that macrolides do not provide anaerobic coverage. An alternative approach would be to use high-dose penicillin plus an aminoglycoside.[64,70]

PROGNOSIS

The prognosis in cases of *A. haemolyticum* pharyngitis is good, even in untreated patients. However, invasive disease can be fatal, and peritonsillar abscess requires prompt surgical intervention and appropriate antimicrobial therapy.

CHAPTER 94

Erysipelothrix Rhusiopathiae

Randall G. Fisher

Erysipelothrix rhusiopathiae (insidiosa) was identified definitively first by Rosenbach[32] in 1884 as a cause of the cutaneous disease erysipeloid. Although most commonly associated with localized skin infection in humans, this organism has been associated with sepsis,[13,30,42] chronic skin eruption,[9,19] and endocarditis.*

BACTERIOLOGY

E. rhusiopathiae is a slender, pleomorphic, gram-positive, unencapsulated rod that produces 0.1-mm bluish colonies on blood agar. On Gram staining, the rods may appear singly, in short chains, or, rarely, in long, branching filaments. Although they are gram positive, they decolorize readily, sometimes producing a spotted appearance. Some strains produce α-hemolysis in 48 to 72 hours. Gelatin inoculated by stab inconsistently forms a "test-tube brush" or "pipe cleaner" appearance diagnostic for this organism.[13] *Erysipelothrix* is differentiated from morphologically similar *Listeria monocytogenes* and diphtheroids by the absence of motility and catalase production and by the presence of hydrogen sulfide production in triple-sugar iron medium.[13,42]

EPIDEMIOLOGY

First isolated from mice in 1880 by Koch, *Erysipelothrix* is a common commensal of wild and domestic mammals, birds, and fish.[13,42] The organism also may lead a saprophytic existence in soil. First identified by Loeffler in 1882 as the causative agent of swine erysipelas, it remains an important epidemic cause of disease in these animals, with losses greater than $25 million annually to this industry.[13] Sheep, rabbits, cattle, turkeys, and rats are subject to infection with this organism. *Erysipelothrix* has been recovered from wild moose and domestic emus.[5,14,23] *E. rhusiopathiae* survives salting and smoking procedures. Pieces of meat may contain the organism for 170 days after pickling, but exposure to moist heat for 15 minutes at 55° C kills most strains.[13,40] Fish handlers, meat processors, poultry workers, veterinarians, abattoir workers, and food handlers are at risk for exposure to *Erysipelothrix*.[26,28] Isolates of the same serotype may show genetic diversity, thus serotyping may not be completely reliable as an epidemiologic tool for tracking outbreaks.[6]

PATHOPHYSIOLOGY

Human infection is largely accidental and results from contamination of skin abrasions during handling of infected material. Males are infected more commonly than females, perhaps because of an increased risk for exposure. The presence of an antiphagocytic capsule may be a virulence factor for *E. rhusiopathiae*.[35] In vitro study shows that encapsulated strains are poorly phagocytized by macrophages, unless immune serum is provided; ingested bacteria are able to replicate within the macrophage. The ability to survive and replicate within macrophages probably is due to failure of the encapsulated strains to induce the oxidative burst.[34] The disease usually is self-limited, most often involving the hands. Biopsy of skin lesions shows a marked inflammatory response. Difficulty of establishing bacteriologic confirmation has been attributed to the organism's location in the deep part of the pars reticularis of the corium.[7]

CLINICAL MANIFESTATIONS

Human disease typically manifests as a mild, localized cutaneous eruption; a more severe, generalized cutaneous

form; or a septicemia often associated with endocarditis. Localized cutaneous infection, the erysipeloid of Rosenbach,[32] is the most common manifestation of *Erysipelothrix* disease.[28] After a 1- to 4-day incubation period, an acute localized lesion appears at the site of an abrasion contaminated with *E. rhusiopathiae*–colonized material. Slowly progressive, purplish red, painful induration is typical. Absence of suppuration and involution without desquamation help to distinguish this lesion from streptococcal or staphylococcal infection. Occasionally, the skin may show sharply circumscribed bluish red lesions, which are similar to the cutaneous manifestations in swine.[13,42] Fever and other constitutional symptoms are uncommon manifestations, occurring in less than 10 percent of cases, unless bacteremia supervenes.[9,28] Untreated infection usually is self-limited, with an average duration of 3 weeks.

Lymphangitis and adenitis occur in 10 percent of cases; in 20 percent of cases, progression of disease extends from lesions on the hand to the wrist and forearm.[20] In one case, a patient with type 2 diabetes was discovered at the time of surgery to have necrotizing fasciitis; *E. rhusiopathiae* was the predominant but not only organism isolated from surgical specimens.[36] A 7-week-old infant with localized *E. rhusiopathiae* infection of the knee without a known source of exposure has been reported,[22] and a 6-year-old girl with *Erysipelothrix* pyopneumothorax has been described.[29] Septic arthritis has been described in a healthy 18-year-old man in whom disease developed after he underwent arthroscopic knee surgery,[2] in association with infective endocarditis,[33] and in a patient with systemic lupus erythematosus and chronic monarthritis without associated systemic symptoms.[41]

Cutaneous eruptions rarely may occur in areas distant from the site of inoculation,[21] appearing as violaceous lesions with advancing pink borders. Bullous vesiculation has been described.[9] In 1921, Prausnitz[30] reported the first case of apparent septicemia in childhood, isolating the organism from the blood of a 10-year-old boy.

E. rhusiopathiae rarely is associated with the bite of a domestic dog or cat.[1] In one prospective study of infected domesticated animal bite wounds, two patients who had been bitten by a cat infected with *E. rhusiopathiae* were identified.[37] Cultures were carefully processed and were performed in reference laboratories.

An uncommon but important complication of *Erysipelothrix* infection is endocarditis. Presumed or proven endocarditis accounts for 90 percent of serious *E. rhusiopathiae* infection.[12] Patients with congenital heart disease or heart valve damage secondary to acute rheumatic fever are at the greatest risk for development of endocarditis. However, previously normal heart valves can be infected.[13,24] Valvular and myocardial abscesses have been described.[27] In contrast to diphtheroid endocarditis, *E. rhusiopathiae* endocarditis usually does not involve prosthetic valves; and in contrast to *Bacillus* spp. endocarditis, it is not associated with intravenous drug abuse.[12] In a review of 1989 cases of endocarditis from 13 series,[3] *Erysipelothrix* was documented in two patients. *Erysipelothrix* endocarditis commonly involves the aortic or mitral valves or both. Overall mortality in reported cases is 38 percent, which is considerably higher than that associated with other pathogens of endocarditis.[11] Many patients with endocarditis are treated empirically with vancomycin, a drug to which all *Erysipelothrix* isolates are constitutively resistant.[16] No history nor physical evidence of cutaneous lesions is found in 50 percent of cases of endocarditis, and history of exposure to contaminated material often is lacking. Although immunocompromised individuals[25] may be at increased risk, serious infection also occurs in otherwise normal hosts,[4,13,24] particularly in association with occupational exposure.

Multiple case reports of septic arthritis, usually involving prosthetic joints, have been published.[15,38,39] Meningitis is rare and may be acute[17] or chronic.[18]

DIAGNOSIS

For localized disease, diagnosis depends largely on clinical appearance of the lesion in association with an appropriate history of exposure. Attempts to culture the organism from material collected by swab or aspirate of a local lesion almost always are unsuccessful, presumably because of the bacteria's location deep within the skin.[7,42] Biopsy specimens of affected skin cultured in broth generally yield the offending bacteria. Amplification and detection of *Erysipelothrix* DNA by polymerase chain reaction show promise in animal models of infection.[23] *Erysipelothrix* is isolated commonly from the blood of patients with septicemia or endocarditis and can be found in affected heart valves at autopsy or at the time of valve replacement.[9] Growth of the organism may be slow; cultures should be monitored for at least a week. A high index of suspicion is important for establishing the diagnosis of endocarditis. The organism has been misidentified as a viridans group streptococcus because of its pleomorphic coccoid appearance, α-hemolysis, and catalase-negative character. Abbreviated identification schema that do not include testing for hydrogen sulfide production sometimes lead to misidentification as *Lactobacillus* spp. or enterococci.[8]

TREATMENT

E. rhusiopathiae is exquisitely sensitive to penicillin. Most isolates also are sensitive to ceftriaxone.[10] Clindamycin or ciprofloxacin may be used for patients who are allergic to penicillin.[10] Localized disease usually can be treated with oral medication, but high parenteral doses occasionally are necessary, particularly for disseminated disease.[13] Treatment of endocarditis is similar to treatment of endocarditis caused by viridans streptococci. At least 12 million units of penicillin administered for 4 weeks has been curative in adult patients, but many cases have been treated for 6 weeks or longer. Concomitant administration of an aminoglycoside has been used in some cases. *Erysipelothrix* is resistant to vancomycin.[16] Prompt microbiologic differentiation of *E. rhusiopathiae* from other gram-positive organisms is important in guiding antimicrobial choice because vancomycin often is employed in empirical therapy for endocarditis. Risk for acquiring

disease is minimized by protecting individuals exposed to potentially contaminated materials.

CHAPTER 95

Listeriosis

Tobias Kollmann • Robert Bortolussi • Timothy Mailman

Listeria monocytogenes is found widely in the environment in soil, water, and decaying vegetation.[3,42,108] Infection with *L. monocytogenes* was described first by Murray and associates in 1926 while they were investigating an epidemic of perinatal infection in laboratory rabbits.[91] Human disease caused by *L. monocytogenes* was identified 3 years later,[92] and neonatal infection was identified in 1936.[15] The first outbreak confirming transmission from animals to humans was reported in 1983.[109] *L. monocytogenes* since has been found to be a serious, lethal pathogen especially for neonates, pregnant women, the elderly, and immunocompromised individuals.[12,25,73] The recent upsurge in outbreaks has refocused attention on this organism.*

THE ORGANISM

Listeria comprise regular, short, facultatively anaerobic, non–spore-forming, gram-positive rods that are motile and form bluish gray colonies on nutrient agar. They are non–acid fast and catalase positive and do not form capsules. The genus is named in honor of *Lister*, the pioneer of antiseptics. Of the six *Listeria* spp. (*L. monocytogenes*, *Listeria innocua*, *Listeria grayi*, *Listeria welshimeri*, *Listeria seeligeri*, and *Listeria ivanovii*), *L. monocytogenes* is the major pathogen.[55,81] The few case reports regarding other species causing infection usually involve immunocompromised hosts.[105] The following features of *L. monocytogenes* separate it from nonpathogenic *Listeria* spp. as well as other gram-positive rods[114]:

1. All *Listeria* species exhibit tumbling motility at 25° C to 30° C, owing to peritrichous flagella, with reduced motility at 37° C (98.6° F).
2. *L. monocytogenes* grows with a narrow zone of β-hemolysis (nonhemolytic strains exist but are rare) and exhibits a rectangular area of increased hemolysis when streaked on blood agar in proximity to *Staphylococcus aureus* (Christie, Atkins, Munch-Peterson [CAMP] test).
3. *Listeria* are catalase positive.
4. *L. monocytogenes* ferments methyl-D-mannoside and L-rhamnose but not D-xylose.

Listeria tolerate low temperatures, high salt concentrations, and high pH, which allows replication in soil, water, sewage, manure, animal feed, and, significantly, refrigerated foods. Cold enrichment has been used to improve isolation from clinical samples.[9,41,55,113]

Paterson[96] and Seeliger and Finger[115] performed extensive serologic characterization of *L. monocytogenes*. At least 17 serotypes have been identified on the basis of somatic and flagellar antigens, with 3 (1/2a, 1/2b, 4b) accounting for most clinical and food isolates.[84,98]

TRANSMISSION

The ability of *L. monocytogenes* to tolerate high salt concentrations and an alkaline environment allows it to survive for months in soil, water, animal feed, and refrigerated foods.[23] Contaminated food is a common source of severe human *Listeria* infection.[17,51,71] In spite of earlier successes in controlling foodborne *L. monocytogenes* infection, the incidence remains high.[17] *L. monocytogenes* still is the most common cause of foodborne illness related hospitalization and death in the United States.[17] Yet most infections are sporadic and have no epidemiologic explanation.[130] Furthermore, asymptomatic fecal carriage in healthy individuals is common with a prevalence reported at 2 to 10 percent[108] or higher.[61,73] Dissemination of *L. monocytogenes* from colonized humans may play a role in transmission.[30] Although maternal colonization does not invariably lead to invasive illness, pregnancy-associated infection represents approximately 17 percent of all invasive cases.[58] About 20 percent of pregnancy-associated infection results in fetal loss or neonatal death.[58] Transmission of *L. monocytogenes* from mother to fetus can occur in utero by inhalation or ingestion of infected amniotic fluid or transplacentally from the maternal circulation.[73] However, the factors contributing to most cases of late-onset infection of the newborn (up to 2 months of age) are unknown.[10,63,100] Nosocomial transmission has also been described.[35,49,74,112]

EPIDEMIOLOGY

Despite its ubiquitous presence, and regular outbreaks, *L. monocytogenes* is a relatively uncommon cause of infection in the general population (ranging from 0.1 to 11.3/1 million population).[12,25,40,104,121] Listeriosis has a nonuniform age distribution, with most cases occurring in newborns or elderly individuals (Fig. 95-1). Furthermore, symptomatic listeriosis has a disproportionately high mortality rate in the unborn, the newborn, and the elderly, ranging from 20 to over 60 percent.[104] Invasive *L. monocytogenes* infection is 20- to 100-fold more common in pregnancy than in the general population.[47,58,73] Perinatal attack rates during outbreaks are extremely high and can reach 1 to 2 percent of all deliveries.[10,100] Although preventative measures, monitoring, and voluntary recall of contaminated food products have resulted in reduced perinatal listeriosis in recent decades,[73] risk for foodborne infection remains high and incidence in older adults has, in fact, increased.[10,86,104]

PATHOGENESIS AND PATHOLOGY

Infection with *L. monocytogenes* begins with the ingestion of the bacteria. In adults, the infectious dose is estimated to be 10^4 to 10^6 organisms per gram of ingested food but may be as low as 10 organisms in immunocompromised hosts and patients who have diminished gastric acidity or injured intestinal lining.[10,107,108,110] *L. monocytogenes* infects intestinal M cells through phagocytosis and intestinal epithelial cells through actions of listerial surface proteins called internalin A (InlA).[39,78] InlA binds to host E-cadherin that is transiently exposed to the luminal surface of the intestinal villi during remodeling of epithelial junctions.[97] InlA is possibly also involved in the crossing of the placental barrier because E-cadherin is expressed on syncytiotrophoblasts.[8,79] After infection of the intestinal epithelium, *L. monocytogenes* translocates and reaches the liver, spleen, mesenteric lymph nodes, and other organs via the blood and lymph.[131] Binding of listerial internalin B (InlB) to the host hepatocyte growth factor receptor (also known as the tyrosine kinase receptor Met) and complement component C1q[6] permits efficient hepatocyte entry via endocytosis.* InlB may also

*References 13, 14, 29, 50, 66, 95.

have a role facilitating the transfer of *L. monocytogenes* across the blood-brain barrier.[6,50]

After cell entry, *L. monocytogenes* eventually escapes from endocytic vacuole and replicates in the cytosol of the host cell; from there it spreads to neighboring cells, avoiding destruction by antibodies or neutrophils.[72] This vacuolar escape is assisted by two virulence-associated bacterial molecules: listeriolysin O (LLO) and phospholipase C.[23] LLO is a pore-forming cholesterol-dependent cytolysin and one of the major virulence determinants of *L. monocytogenes*.[5,64,111,132] Although LLO is absolutely required for vacuolar escape in murine cells, it appears dispensable in human cells, where phospholipases are more centrally involved instead.[99] Once in the cytoplasm, *L. monocytogenes* induces polymerization of host actin filaments; this mobility allows it to avoid intracellular degradation (autophagy) and to spread from cell to cell.[88,124-126] Although ActA is one of the major virulence determinants of *L. monocytogenes*,[27] strains lacking ActA retain the ability to infect the placenta, although at a lower rate than wild-type strains.[77]

From the moment *L. monocytogenes* adheres to a target host cell, a response is set into motion that aims to restrict bacterial invasion and survival.[23,129] This has been best studied in the mouse macrophage, where *L. monocytogenes* activates at least three pathways[137]: (1) a MyD88-dependent pathway emanating from the cell surface and phagosome leading to expression of cytokines and reactive oxygen species; (2) a STING/IRF3-dependent pathway emanating from the cytosol leading to the expression of interferon-γ (IFN-γ) and co-regulated genes; and (3) an AIM2/caspase-1–dependent inflammasome pathway resulting in proteolytic activation and secretion of interleukin (IL)-1 and IL-18 and pyroptotic cell death. *L. monocytogenes*, on the other hand, has evolved elaborate mechanisms trying to counterbalance these host defense strategies.[26] The outcome of this molecular tug of war depends on the bacterium, the host cell, and the host. Cytokines and chemokines released by the infected cells recruit neutrophils, which in turn destroy extracellular bacteria and digest dying cells.[68] Infected murine macrophages for example produce IL-12p70, which induces the synthesis of IFN-γ by natural killer cells and CD4 T helper-1 cells; IFN-γ in turn activates infected macrophages to become listericidal through the production of free oxygen and nitrogen radicals.[94,132] This process also leads to formation of granulomas at sites of infection, thereby "walling off the infection."[116] Although multiple granulomas are characteristic of disseminated disease, the basic pathologic change of suppurative inflammation is more common.[67] These innate immune effector cascades limit the spread of *L. monocytogenes* during the early phase of infection. In the immune-competent host, adaptive T-cell immune responses peak about 1 week after primary infection, leading to complete clearance of infected cells; this process also leads to acquired resistance to subsequent infection (immune memory).[95] Acquired immunity is not dependent on clinical symptomatic infection, because T cells specific for *L. monocytogenes* are frequently present in healthy individuals without a history of listeriosis.*

*References 24, 43, 70, 89, 100, 101.

There are many differences in both innate and adaptive immunity between the pregnant, the neonate, the young adult, and the older adult[22,69,80]; and the host response of the human to *Listeria* has not been studied in sufficient detail to know what specific aspect of immune-mediated protection fails to protect those most susceptible from severe listeriosis. In newborn animals, susceptibility to *L. monocytogenes* is associated with delayed production of innate cytokines, resulting in slower activation of T cells and natural killer cells.[10] In older children and young adults, *L. monocytogenes* infection is rare; however, underlying diseases or medications that interfere with cell-mediated immunity are known to increase susceptibility.* On the other hand, neutropenia and disorders of the humoral immune system (complement or immunoglobulin) are not associated with excessive prevalence of listeriosis.[73] This suggests a central role of at least the innate and adaptive cell–mediated immune system in optimal defense against *L. monocytogenes* in the human host.

CLINICAL MANIFESTATIONS

Most infections with *L. monocytogenes* in the healthy host remain entirely asymptomatic.[10] Clinical symptomatic infection with *L. monocytogenes* is called "listeriosis"[107] and exists in two forms depending on the immunologic status of the host—noninvasive gastrointestinal listeriosis and invasive listeriosis.[10,104,132] In immunocompetent children and adults, noninvasive listeriosis develops as a febrile gastroenteritis.[107,110] However, in vulnerable groups, namely, the pregnant female and unborn fetus, neonates and infants up to approximately 2 months of age,[136] the elderly (>60 years of age), and some immune-compromised children and adults,[10,1104] *L. monocytogenes* can spread from the gastrointestinal tract into the systemic circulation and from there to other parts of the body.[10] The main target organs are the placenta, liver, and spleen, as well as the central nervous system.[10,30,100,109] This clinical pattern of invasive listeriosis derives from the unique capacity of *L. monocytogenes* to cross the intestinal, blood-brain, and placental barriers.[78]

In pediatric listeriosis, most severe infections occur in the first 2 months of life. The initial clinical features can be divided into early and late-onset diseases, similar to those of group B streptococcal infection (Table 95-1). In 50 to 74 percent of early-onset cases the mother reports a history of an influenza-like illness, with 65 percent reporting fever, 21 percent backache (which may be mistaken for a urinary tract infection), 10 percent headache, 7 percent vomiting and diarrhea, and 4 percent muscle pains or sore throat; however, approximately one third of infected pregnant women may be entirely asymptomatic.[73] Spontaneous abortion occurs in 10 to 20 percent of clinically symptomatic listeriosis cases during pregnancy, with another approximately 50 percent delivering preterm and 11 percent ending in intrauterine fetal demise. Thirty-four percent of infected pregnancies demonstrate fetal distress, and 75 percent display meconium-stained amniotic fluid; microabscesses are frequently histologically evident in infected placentas.[73]

*References 10, 20, 28, 57, 100, 117, 129, 137.

TABLE 95-1 **Clinical and Laboratory Findings of Early-Onset and Late-Onset Neonatal Listeriosis**

Feature	Early Onset[1,2,34,60,73]	Late Onset[2,36,65,73,114]
Median age in days (range)	1 (birth to 6)	14 (7-35)
Male (%)	60	67
Preterm (%)	65	20
Mortality (%)	38 (22-63)	3 (0-10)
Respiratory involvement (%)	38-50	10
Meningitis (%)	24	67-93
Blood isolate (%)	81-88	17-95
Maternal perinatal illness (%)	50-74	0

Early-onset neonatal listeriosis has a high mortality rate (20 to 60 percent); even in those who survive, a significant number (12.7%) develop long-term neurologic sequelae.[10,73] At birth, respiratory distress, apnea, lethargy, and fever are common manifestations; diarrhea, conjunctivitis, and myocarditis also have been described.[10] The respiratory symptoms may mimic symptoms of respiratory distress syndrome. Patchy bronchopneumonic infiltrates, probably caused by aspiration of infected amniotic fluid, may be seen on chest radiographs.[10] Occasionally, discrete roseolar or pustular lesions on the skin and pharynx occur that on histology appear as microabscesses and macroabscesses and contain culturable *L. monocytogenes;* this rash has been termed *granulomatosis infantisepticum* (Fig. 95-2).

The late-onset form of neonatal listeriosis is less common than the early-onset form and usually affects term infants, who appear healthy until the onset of meningitis or, less commonly, septicemia and colitis 1 to 8 weeks after birth.[36,56,65,74] Clinical manifestations of late-onset meningitis are often subtle and include fever, irritability, lethargy, and poor feeding.[65,113] Cerebrospinal fluid findings vary; although pleocytosis usually is significant, not all infections have a polymorphonuclear cell predominance. The maternal history in these cases usually is negative, suggesting postnatal, possibly even nosocomial, exposure in affected infants.[112]

Although the incidence of listeriosis in immunocompromised children is higher, the clinical features are similar to those of nonimmunosuppressed patients with *L. monocytogenes* infection and include most commonly meningitis or septicemia, but rhombencephalitis, brain abscess, arthritis, osteomyelitis, endocarditis, endophthalmitis, liver abscess, and peritonitis may occur as well.[82,112,113,117]

FIGURE 95-2 ■ Typical pustular rash on the abdomen of a stillborn infant with listeriosis. Note the small pale granuloma measuring 1 to 3 mm and the dark erythema surrounding these lesions.

DIAGNOSIS

Appropriate specimens for staining and culture vary with the clinical syndrome, but the organism can be readily cultured from blood, cerebrospinal fluid, amniotic fluid, and genital secretions. Examination of Gram-stained material (ear, meconium, and placenta) from neonates is recommended in suspected, early-onset sepsis.[77] Pathologic specimens (e.g., biopsy material, placental or fetal tissue) may reveal the characteristic Gram-stain morphology and pathologic features, such as microabscesses and granulomas. Selective culture media, such as PALCAM (polymyxin B–acriflavine–lithium chloride–ceftazidime–esculin–mannitol agar) or modified Oxford agar, may be helpful for isolation from nonsterile sites such as stool or vaginal secretions.[83,98] Laboratories undertaking primary isolation must be aware of the similarities between *L. monocytogenes* and frequently discarded "commensals."[84]

After 48 hours of incubation at 37°C on 5 percent sheep blood agar, typical colonies are gray with a narrow zone of β-hemolysis. The appearance of short *Listeria* rods on Gram stain has been confused with lancet-shaped pneumococci. Traditionally, identification is based on morphology; tumbling motility; β-hemolysis; positive catalase, esculin, and CAMP tests; and carbohydrate use pattern. Commercial kits are available for the rapid identification of *Listeria* from culture. These kits include DNA probes, latex agglutination, and enzyme immunoassay methods. Despite extensive attempts to develop serologic techniques for the diagnosis of listeriosis,

none has proved satisfactory and few centers attempt serodiagnosis.

Histologic diagnosis from pathologic material should be attempted if the organism is not cultured. Specific fluorescent antibody staining,[18] nucleic acid hybridization,[120] and polymerase chain reaction[4,59] have all been used for detection of *Listeria*. The application of molecular detection to food safety programs has been growing rapidly, with clinical applications of molecular *Listeria* detection lagging somewhat behind with regard to the commercial options available. Still, several centers have reported the development of sensitive molecular assays for detection of *L. monocytogenes* from clinical samples, in particular cerebrospinal fluid. For cases of suspected meningitis with prior antibiotic treatment, broad-range 16S polymerase chain reaction is becoming widely used in North America and can be key in establishing the diagnosis.[11,76]

TREATMENT

Intravenous ampicillin and an aminoglycoside, typically gentamicin, remain the treatment of choice for invasive *L. monocytogenes* infections. Ampicillin may be used alone in immunocompetent patients with less severe infections or once clinical response has occurred. Antibiotic resistance in clinical *Listeria* isolates remains low, although surveillance of food and dairy products has shown an increase in resistance to multiple antibiotics including ampicillin.[52,118,135] Although human data for dual treatment are lacking, ampicillin plus gentamicin has demonstrable synergy on most *Listeria* strains both in vitro and in animal models[31,87,127] *L. monocytogenes* shows tolerance to some antibiotics in vitro.[32,85] Antibiotics commonly recommended for treatment—including ampicillin—are bacteriostatic at concentrations usually achieved in blood.[32,44,45,128,133]

For penicillin-allergic patients, trimethoprim-sulfamethoxazole has been used successfully.[51,119] This is supported by in vivo data with and without the addition of rifampin.[37,53,54,87,106] In an in vivo model of *L. monocytogenes* encephalitis, the combinations ampicillin/gentamicin and trimethoprim-sulfamethoxazole/rifampin were highly active against intracerebral bacteria.[7] Trimethoprim-sulfamethoxazole cannot be recommended for use in perinatal infections because of the concern of bilirubin toxicity developing with sulfonamides.[37]

For patients with both penicillin and sulfa allergies, vancomycin has been used successfully, albeit with much less accumulated clinical experience than ampicillin-based regimens.[102] One group has reported a bacteremia with vancomycin-resistant *L. grayi*, the first documented invasive infection with this species.[105]

More recently, cases of invasive *Listeria* infections treated successfully with linezolid have been published.[87,90] This oxazolidinone antimicrobial exhibits bactericidal activity against *Listeria*.

Notably, *L. monocytogenes* is intrinsically resistant to cephalosporin antibiotics.[32] Similarly, resistance to clindamycin, tetracyclines, quinolones, and macrolides is common and clinical experience with these agents is very limited. Antagonism also seems to occur between certain antibiotic combinations (erythromycin and penicillins, erythromycin and aminoglycosides, penicillin and chloramphenicol, and penicillin and tetracycline).[32,44]

Duration of therapy depends on the clinical syndrome, the presence of underlying disease, and the response to treatment. For most invasive infections without meningitis, 10 to 14 days of therapy is usually sufficient. When meningitis is present, many experts recommend 2 to 3 weeks of therapy. Longer courses may be necessary for patients with endocarditis, rhombencephalitis, and severe, complicated infections. When treating central nervous system infections, diagnostic imaging of the brain near the end of anticipated therapy may be used to evaluate the possibility of parenchymal involvement and determine the need for an extended duration of therapy.

Listeria gastroenteritis, in otherwise healthy individuals, is generally a self-limited illness and no data exist with regard to the efficacy of antimicrobial therapy. In high-risk individuals such as pregnant women and those with immunocompromise, who have either symptomatic illness or who are known to have ingested a contaminated food, it may be prudent to administer treatment or prophylaxis with a course of oral amoxicillin or trimethoprim-sulfamethoxazole.[93]

PROGNOSIS

Maternal listeriosis may result in abortion, stillbirth, or early neonatal death.[73] Although the relative risk for fetal death is difficult to estimate, spontaneous abortion rates of 10 to 20 percent and stillborn rates of 11 percent have been noted.[73] Fetal distress and/or meconium staining of amnionic fluid is estimated to occur in 75 percent of perinatal cases.[73] Convincing evidence that *L. monocytogenes* is associated with repeated abortions is lacking.[48]

Among cases of early-onset sepsis, the mortality rate in North America is approximately 40 percent (see Table 95-1).[1,34] Most survivors appear normal at short-term follow up.[33,34,123] Sequelae are related to the associated complications of prematurity, pneumonia, and sepsis; hydrocephalus and cerebral palsy also have been reported.[33,62] Early treatment of maternal disease affects fetal and neonatal outcome favorably.[34,62]

Late-onset *Listeria* meningitis has a mortality rate of less than 10 percent. The outcome after *Listeria* meningitis may be more favorable than the outcome associated with other types of bacterial meningitis.[65,134] Major sequelae are hydrocephalus and mental retardation. Beyond the neonatal period, the outcome of listeriosis depends on the nature of any underlying disease and the availability of intensive medical care. Among adults with no underlying malignancy, the long-term outcome of *Listeria* meningitis is excellent.[103]

PREVENTION

The sporadic nature of the disease in North America emphasized the need for collaborative investigation and reporting of infections by physicians and veterinarians to

public health authorities.[9,41] In the early 1990s, listeriosis became a notifiable disease in the United States and Canada.[98,122] Since then, the important role of food in the transmission of sporadic cases has been firmly established.[113,122] Inspection of food production facilities and dissemination of educational materials may have contributed to a general reduction of outbreaks of listeriosis since then as well.[4,38,46,122] Strict adherence to regulations for pasteurization of raw milk is important to inactivate the organism and prevent listeriosis.[16] Contamination of food can occur during the preparation and processing of pasteurized milk products and ready-to-eat meat or poultry products. The source of an outbreak is sometimes found by tracking strains of *L. monocytogenes* isolated from a patient's food to the retail sources. Recommendations for individuals at high risk, such as pregnant women and immunocompromised patients, include avoiding soft cheeses and delicatessen meats and avoiding reheating leftover foods or ready-to-eat foods (e.g., hot dogs).[98] In spite of this, many hospitals have failed to implement appropriate food preparation policies.[19] During an outbreak of *Listeria*, prompt investigation and treatment of pregnant women with a febrile "influenza-like" illness have been advocated.[9,62] Although treatment of symptomatic mothers may prevent perinatal listeriosis, there is no evidence to show that treatment of colonized infants can either eradicate carriage or prevent infection. Careful attention given to the handling of infected infants in a neonatal unit in an attempt to prevent transmission is important for preventing nosocomial infection.[35,112]

CHAPTER 96

TUBERCULOSIS

Andrea T. Cruz • Jeffrey R. Starke

Tuberculosis ranks as one of the three most important infectious diseases in the world in terms of morbidity and mortality. The disease is recognizable in skeletons from the Stone Age and in mummified corpses from the Egyptian Old Kingdom. For centuries, it was believed that the touch of royalty could cure scrofula. Edward the Confessor (mid-11th century) was one of the first to wash the diseased flesh of his subjects.[228] Although this tradition lapsed with King William III in the late 17th century, it may have contributed to the consumptive deaths of

many members of European royal families. Tuberculosis became more widespread in western Europe after the plague years of the Middle Ages and the epidemic during the era of urbanization and industrialization in the 18th and 19th centuries.[177] At that time, scrofula affected more than half the young inhabitants of workhouses and orphanages.

During the 18th and 19th centuries in the eastern cities of the United States (Boston, New York, and Philadelphia), the mortality rate from tuberculosis was about 400 per 100,000 population. With improving socioeconomic conditions, the mortality rate fell to 200 per 100,000 around 1900 and to 26 per 100,000 by 1950 even before the advent of effective chemotherapy. Stress in all its forms—famine, war, rationing, long working hours, child labor, population displacement, crowded living and working conditions—favors the spread of tuberculosis in humans, whereas years of peace and plenty favor its rapid decline.[176,515] The decrease in the Western world in the incidence of tuberculosis was accentuated by the discovery, development, and widespread use of antituberculosis drugs beginning in the late 1940s.

Another important factor leading to the decline of tuberculosis in Western countries was the recognition in the 1920s of the importance of bovine tuberculosis and its successful eradication as a public health problem in the United States by gradual slaughter of infected cattle and almost universal pasteurization of milk.[220] Although *Mycobacterium bovis* disease now accounts for a small fraction (1% to 2%) of all tuberculosis in the United States,[253] it has been implicated in up to 10 percent of cases in children along border regions of the United States.[144]

STAGES: EXPOSURE, INFECTION, AND DISEASE

The pathophysiologic process of tuberculosis is complicated, and the delay between acquisition of infection and manifestation of disease renders certain pathophysiologic events less distinct.[12] There are three major stages of tuberculosis: exposure, infection, and disease.[616]

Exposure means that the child has had significant contact with an adult or adolescent with infectious pulmonary tuberculosis. The contact investigation—examination of individuals close to a person suspected of having tuberculosis by performing a tuberculin skin test, chest radiograph, and physical examination—is the most important activity in a community to prevent cases of tuberculosis in children.[14,58,265] The most frequent setting for exposure of a child is the household, but it can occur in a school, daycare center, or other closed setting.[153,257] In this stage, the tuberculin skin test result is negative, the chest radiograph is normal, and the child lacks signs or symptoms of disease. Some exposed children may have inhaled droplet nuclei infected with *M. tuberculosis* and have early infection, but the clinician cannot know it because delayed hypersensitivity to tuberculin—a positive skin test response—takes up to 3 months to develop. Children younger than 5 years old or immunocompromised children of any age who are in the exposure stage should be treated to prevent the rapid development of disseminated or meningeal tuberculosis, which can occur before the skin test becomes reactive.[184,371,462,493,631]

Infection occurs when the individual inhales droplet nuclei containing *M. tuberculosis*, which becomes established intracellularly within the lung and associated lymphoid tissue. The hallmark of latent tuberculosis infection is a reactive tuberculin skin test or a positive interferon gamma release assay (IGRA). In this stage, the child has no signs or symptoms and the chest radiograph is either normal or reveals only granuloma or calcifications in the lung parenchyma or regional lymph nodes or in both tissues. In industrialized countries, virtually all children with tuberculosis infection should receive treatment, usually with isoniazid, to prevent the development of disease in the near or distant future.

Disease occurs when signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. The word *tuberculosis* refers to disease. Not all infected individuals have the same risk for contracting disease. An immunocompetent adult with untreated tuberculosis infection has a 5 to 10 percent lifetime risk for development of disease; half the risk exists in the first 2 to 3 years after infection occurs. Adults with tuberculosis infection who then become infected with human immunodeficiency virus (HIV) have a 5 to 10 percent annual risk for development of tuberculosis disease.[564] Historical studies have shown that often serious, life-threatening forms of the disease will develop within 1 to 2 years in as many as 40 percent of immunocompetent infants with untreated tuberculosis infection.[395]

EPIDEMIOLOGY

Incidence and Prevalence

Between 20 and 45 percent of the world's population (approximately 2 billion people) are infected with *M. tuberculosis*, and more than 90 percent of new cases occur in the developing world. The World Health Organization (WHO) estimates that 8.8 million incident cases, 12 million prevalent cases, and 1.45 million deaths from tuberculosis occur annually worldwide.[713] The annual rates per 100,000 persons are 128 for incidence, 178 for prevalence, and 15 for mortality, respectively.[713]

Steps toward tuberculosis elimination have been thwarted by the HIV pandemic. Each disease makes the other more difficult to treat, and diagnosing tuberculosis in HIV-infected patients is challenging. It has been estimated that 13 percent of persons with tuberculosis are coinfected with HIV,[713] although there is wide variation. The highest rates of HIV coinfection are seen in sub-Saharan Africa, where up to 40 percent of newly diagnosed tuberculosis patients have HIV infection.[713] Approximately one fourth of deaths from tuberculosis occur in HIV-infected persons,[713] and tuberculosis is the most common infectious cause of death in HIV-infected persons, particularly in patients with high CD4 cell counts.[23] True rates of HIV and tuberculosis coinfection are unclear, because many nations do not screen all newly diagnosed tuberculosis patients for HIV.

According to the WHO, in 1997, only 32 percent of the world's population lived in areas where effective tuberculosis control programs were fully operational.[457] Poor tuberculosis control selects for drug-resistant isolates. Multidrug-resistant tuberculosis (MDR-TB), where the isolate is resistant to at least isoniazid and rifampin, and extensively drug-resistant tuberculosis (XDR-TB),[572] with resistance to isoniazid, rifampin, non-streptomycin injectable drugs, and fluoroquinolones, have become important problems in many areas of the world.[183,713,726] MDR-TB was not described until 1990[91] but has spread widely. In adults, drug resistance in *M. tuberculosis* often is secondary, the resistance emerging during therapy because treatment is inadequate or interrupted.[206] In children, drug resistance usually is primary in that the child is infected with a strain that already has become resistant.[460,546,548,645] Rates of drug resistance in children tend to mirror those in adults in the same population[622,623] and may be higher in developing countries because of difficulty in completing therapy, inadequate supply of medications, and use of over-the-counter cough medications that often contain isoniazid or rifampin. Although 4 percent of tuberculosis cases globally (650,000 estimated MDR-TB cases in 2010)[713] are MDR-TB, rates as high as 23 to 26 percent have been reported in countries formerly part of the Soviet Union.[713,715] The true rates of drug-resistant tuberculosis are unclear. Limitations to accurate estimates include variation in laboratory capacity and reporting and selection of particular patients for drug susceptibility testing (e.g., patients who are failing standard therapy). Additionally, not all patients have culture-confirmed tuberculosis. Finally, the manner in which rates are reported is important. Although incident cases are a better marker of spread of strains in the community, prevalence rates provide a better reflection of the chronicity of MDR-TB and XDR-TB.

In developing countries where the burden of disease is greatest, the only available diagnostic test often is an acid-fast smear of sputum, the result of which rarely is positive from infants and children with pulmonary tuberculosis. This leads to underestimation of the pediatric tuberculosis disease burden. Up to 11 percent of deaths from adolescence to early adulthood are attributable to tuberculosis and HIV infection/AIDS in high-prevalence areas.[489] In areas with both accurate reporting and high rates of tuberculosis, it is thought that children younger than 15 years of age comprise 15 to 20 percent of the disease burden.[399] This figure varies widely among countries: although only 6 percent of all cases in the United States occur in children,[103] children are reported to account for 1.4 percent (Nigeria) to 17 percent (Swaziland) of cases in sub-Saharan African nations.[714] Approximately 81 percent of childhood cases occur in the 22 countries with the highest burden. There also are indirect impacts of tuberculosis on child health. It has been estimated that 9.7 million children were orphaned in 2009 after at least one of their parents died of tuberculosis.[713] The inability to control tuberculosis despite the availability of effective, relatively inexpensive therapy is one of the greatest medical failures of our time.[239,615]

The situation in the United States is markedly different. Between 1953, when reporting began, and 1985, the number of annually reported tuberculosis cases in the United States fell by 74 percent from 84,304 to 22,201.[96] In 1985, the overall case rate was approximately 10 per 100,000 population. Between 1985 and 1992 in the United States, the total tuberculosis case numbers rose 20 percent.[96] During that same time, the number of pediatric tuberculosis cases rose 40 percent[294,669] (Fig. 96-1). Most experts cite four probable causes for the increases: (1) the co-epidemic of HIV infection; (2) the increasing rates of tuberculosis in foreign-born individuals in the United States[78]; (3) the increased transmission among adults in congregate settings, including jails and prisons, nursing homes, homeless shelters, HIV treatment facilities, hospitals, and, rarely, schools[40,43,60,418]; and (4) a decline in the public health infrastructure in many areas of the country.[73,123,516,617] After several years of intense and expensive effort were expended, the number of tuberculosis cases in the United States declined again.[447]

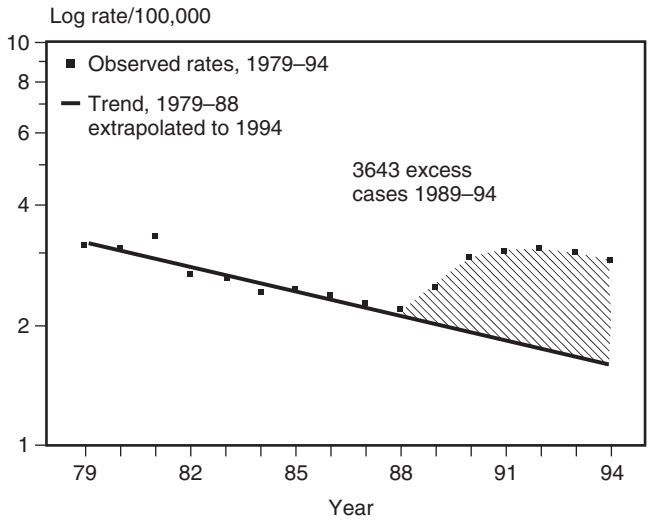

FIGURE 96-1 ■ Observed and expected tuberculosis cases in children younger than 15 years old in the United States, 1979 to 1994.

In 2011, a total of 10,521 incident tuberculosis cases (3.4 cases per 100,000 population) were reported in the United States, the lowest reported rate since 1953.[103] Since treatment became available in the late 1940s, tuberculosis has been concentrated in certain high-risk groups in the United States[97] (Table 96-1). Tuberculosis occurs most commonly in areas with ethnically diverse populations, including large urban areas, coastal states, and states bordering Mexico[90,98] (Fig. 96-2); California, Florida, New York, and Texas accounted for almost one half of all U.S. tuberculosis cases in 2011.[103] Tuberculosis disproportionately affects ethnic and minority populations in the United States. In 2011, when compared with non-Hispanic whites, tuberculosis rates among Hispanics, non-Hispanic blacks, and Asians were 7, 8, and 25 times greater, respectively.[103] In 2011, the Centers for Disease Control and Prevention (CDC) reported the highest overall number of cases (3147) and case rates (21.4/100,000) in Asians.[103]

The majority (62.5%) of cases of tuberculosis in the United States occur in foreign-born persons, who have rates of tuberculosis 12 times higher than persons born

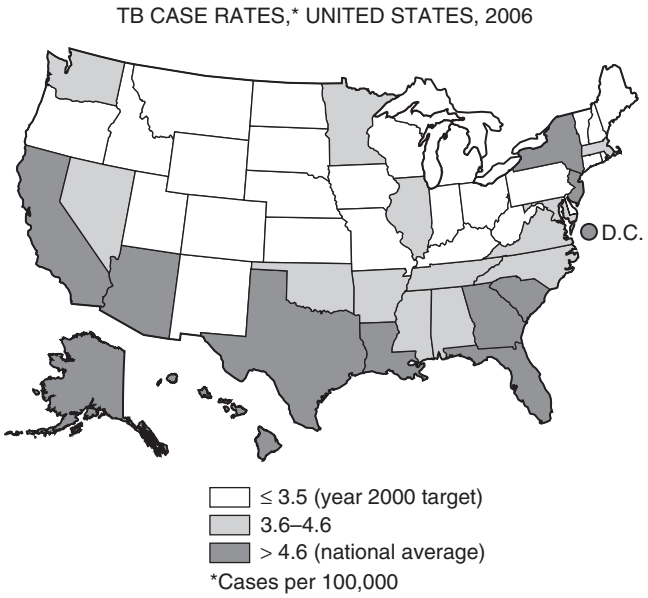

FIGURE 96-2 ■ Tuberculosis case rates (cases per 100,000) by state, 2006. (From Centers for Disease Control and Prevention. *Reported tuberculosis in the United States, 2006*. Atlanta, Ga.: U.S. Department of Health and Human Services, CDC; October 2007.)

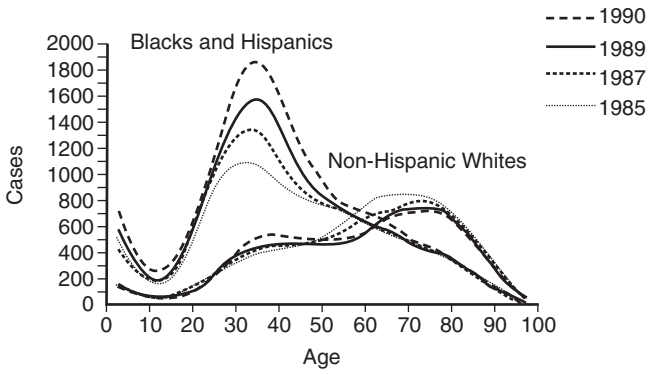

FIGURE 96-3 ■ Tuberculosis cases in Hispanics and blacks versus non-Hispanic whites in the United States, 1985 to 1990.

TABLE 96-1 High-Risk Groups for Tuberculosis Infection and Disease

Groups at High Risk for Exposure or Infection
Close contacts of person with tuberculosis
Foreign-born persons from high-risk countries (Asia, Africa, Latin America, Russia, Eastern Europe)
Residents and employees of high-risk congregate settings (correctional institutions, nursing homes, homeless shelters, hospitals serving high-risk populations, drug treatment centers)
Medically underserved, low-income populations
High-risk racial or ethnic minority populations
Injection drug users
Children exposed to adults in high-risk categories
Groups at Higher Risk for Disease Once Infected
Immunosuppressed patients, including those HIV infected
Recent tuberculosis infection (within past 2 years)
Persons with certain medical conditions (diabetes mellitus, silicosis, cancer, end-stage renal disease, gastrectomy, body weight ≤90% of ideal)
Injection drug users
History of inadequately treated tuberculosis
Children age ≤4 years, especially infants

in the United States.[103] Tuberculosis is endemic in most developing countries, and between 30 and 50 percent of recent immigrants to the United States have latent tuberculosis infection on entry into the country.[119,642] During the immigration process, adults are screened for tuberculosis disease with a chest radiograph, but skin testing to detect tuberculosis infection is not required. Among children in the United States, being born in a country with a high rate of tuberculosis is the most important risk factor for having tuberculosis infection. Foreign-born adopted children also are at risk for having tuberculosis infection and disease.[205,346,531] People who enter the United States illegally may be unable or afraid to seek medical treatment, even when they are ill. Studies have shown that in most immigrants in whom tuberculosis develops, it does so within 5 years of immigration, thus indicating that many cases could be prevented if appropriate screening and treatment programs were conducted.

Other important risk factors for tuberculosis in adults include lower socioeconomic status, migrant work, HIV infection, drug use, homelessness, travel to high-prevalence countries, history of incarceration, and occupations with exposure to high-risk populations (see Table 96-1). Children from high-risk population groups or children who have contact with adults in these groups may be at increased risk for development of tuberculosis infection.[369] Age has an important influence on tuberculosis case rates.[451] During 2010, 6 percent of cases in the United States occurred in children younger than 15 years, 11 percent in persons 15 to 24 years old, 33 percent in persons 25 to 44 years old, 31 percent in persons 45 to 64 years old, and 20 percent in persons older than 64 years.[103] The highest case rates among children are in those younger than 5 years. Children aged 5 to 14 years, the so-called favored age, have a consistently lower case rate than that of any other segment of the population.[393,451] In early childhood, the incidence is not significantly different in girls and boys, although higher rates of disease are generally experienced by adolescent girls than adolescent boys.[69]

The age at which tuberculosis disease initially develops currently varies among ethnic groups in the United States.[95] White persons develop tuberculosis more commonly as older adults, whereas African Americans and Hispanics have a higher incidence of disease as young adults or children (Fig. 96-3).[632] Many of the risk factors for development of tuberculosis, such as HIV infection, drug use, history of incarceration, and recent immigration, occur more commonly in young adults in their 20s, 30s, and 40s, a time when contact with children is more likely. Other factors, including recent immigration, socioeconomic status, high-risk behavior, and possibly genetic susceptibility, may influence the peak age distribution of tuberculosis among different groups.[384]

Inherited susceptibility to tuberculosis may contribute to differences among various ethnic groups.[384] Laboratory animals and humans have been shown to differ in genetic susceptibility to tuberculosis.[376,567] In the United States, highly urbanized immigrants, such as Jews from European ghettos, fared much better than did their rural Irish and African counterparts, presumably because generations of exposure to tuberculosis in previous European epidemics had selected in favor of more resistant individuals.[503] As the disease spread to other continents, previously unexposed populations may have been more susceptible to tuberculosis and experienced higher rates of disease.

Cross-sectional prevalence of tuberculosis infection is difficult to ascertain, because this primarily has been described in high-risk groups. One 2011 review found tuberculosis infection in up to 20 percent of foreign-born persons, 13 to 32 percent of homeless individuals, 28 percent of injection drug users, and 2 to 17 percent of prisoners.[262] An estimated 4 to 6 percent of the U.S. population, or approximately 11 million people, are infected with *M. tuberculosis.* The percentage of infected Americans varies widely by racial and ethnic groups and socioeconomic status. Foreign-born persons residing in the United States had a prevalence of infection of 19 percent; African-Americans, 7 percent; Mexican-Americans, 9 percent; and persons living in poverty, 6 percent.[45] This group of infected persons represents a large reservoir from which cases of tuberculosis disease will emerge in the future if these individuals are not treated.[6]

In some U.S. locales that have had recent increases in tuberculosis, the demographic groups with the greatest tuberculosis morbidity also have large numbers of HIV-infected persons.[114,256,448] Sixty to 70 percent of persons with tuberculosis are screened for HIV, and HIV seroprevalence in tuberculosis patients is 6 to 9 percent in the United States.[103] Data on HIV coinfection are incomplete, because HIV screening is not mandatory for tuberculosis patients and is not reported to the CDC by all states. The HIV epidemic has had a profound effect on the epidemiology of tuberculosis in children by two mechanisms[541]: (1) most important in the United States, HIV-infected adults with tuberculosis may transmit *M. tuberculosis* to children in their environment and tuberculosis disease will develop in some of them[326]; and (2) important in many developing countries, children with HIV infection are at increased risk for progressing from asymptomatic tuberculosis infection to disease.[275,375] Several studies have demonstrated increased rates of childhood tuberculosis associated with increased rates of disease among HIV-infected adults in the community.[238,299] Tuberculosis probably is underdiagnosed in HIV-infected children, especially in the developing world, because of the similarity of its clinical manifestations with other opportunistic pulmonary diseases and the difficulty of confirming the diagnosis with the skin test or culture. All children with suspected tuberculosis disease should have HIV serotesting because the two infections are linked epidemiologically and many experts prolong treatment in HIV-infected children with tuberculosis.[231,549,702]

In addition to the association with HIV, the resurgence of tuberculosis in the United States between 1985 and 1992 was associated with the emergence of MDR-TB.[726] MDR-TB mortality rates may be as high as 50 percent in complicated cases.[217,283] Since 1993, the incidence of resistance to isoniazid has remained stable and the incidence of MDR-TB has decreased. In 2010, 8 percent of U.S. isolates were resistant to at least isoniazid and 1.2 percent were MDR-TB. Over 80 percent of cases of MDR-TB occurred in foreign-born persons. XDR-TB has been uncommon in the United States, with five cases reported in 2008, none in 2009, and one in 2010.[103]

Children comprise a small fraction of tuberculosis cases in the United States, in part because of low rates of coinfection with HIV and because the United States has a different population structure than many developing nations. The site of manifestation of tuberculosis disease differs between adults and children. Although pulmonary disease is most common for all ages, extrapulmonary tuberculosis occurs more often in children.[451] Because HIV coinfection increases the risk for development of extrapulmonary disease, rates have increased in adults during the past 15 years. In general, 25 percent of pediatric cases are extrapulmonary, with 75 percent being pulmonary. In 1985, before widespread HIV infection occurred, 85 percent of adults had pulmonary disease and 15 percent had extrapulmonary disease. With the spread of HIV infection, these numbers have shifted; and in recent years, the CDC reported that 78 percent of all new cases, including those in adults and children, were pulmonary and 22 percent were extrapulmonary.[103] Comparison of the site of extrapulmonary disease in children and adults in 1985, before the AIDS epidemic, shows some important differences. First, approximately 70 percent of extrapulmonary tuberculosis in children involved the lymph nodes, as opposed to 25 percent in adults (Fig. 96-4). Second, tuberculous meningitis accounted for 13 percent of extrapulmonary disease in children versus 4 percent in adults. Genitourinary involvement occurred in 16 percent of adults, but it was a rare finding in children. Although the proportion of extrapulmonary cases in adults has increased as a result of the HIV-AIDS epidemic, extrapulmonary disease still occurs more commonly in children.

Transmission

Transmission of tuberculosis is from one human to another, usually through infected droplets of mucus that become airborne when an individual coughs, sneezes, or laughs.[113] The droplets dry and become droplet nuclei, which may remain suspended in air for hours. Only particles less than 10 μm in diameter are small enough to reach the alveoli.[542] Transmission sometimes occurs by direct contact with infected discharges (sputum, saliva, urine, or drainage from an open sinus or abscess); it occasionally occurs by means of heavily contaminated fomites, such as shoes, gastric lavage tubes, bronchoscopes, or syringes prepared by someone with positive sputum.[252] Rare cases of tuberculosis transmitted by a lung or kidney transplant have been reported.[101,446] Dogs may be a source of infection for children because dogs

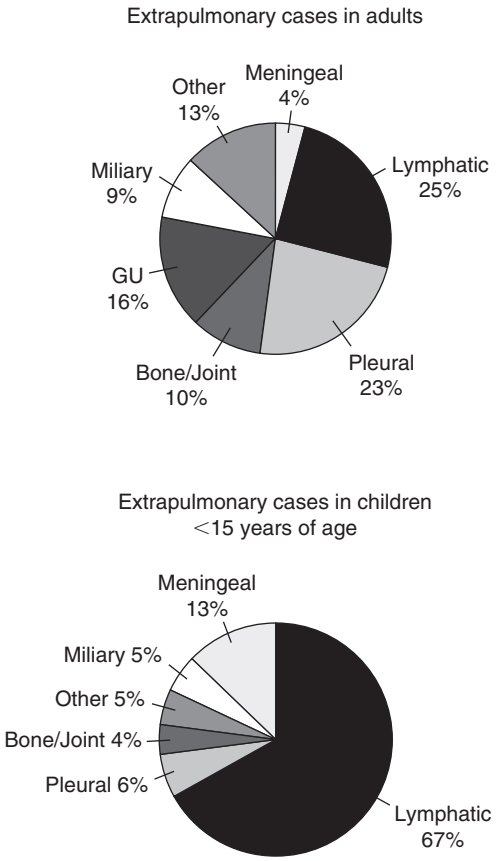

FIGURE 96-4 ■ Extrapulmonary disease by site in adults and children in the United States. (From the Centers for Disease Control and Prevention.)

are susceptible to the human type of tubercle bacillus.[521] One necropsy study showed that the prevalence of tuberculosis disease and infection in dogs in a high-prevalence setting (South Africa) was 1 percent and 50 percent, respectively.[487]

The collective experience of many clinicians is that children usually are infected by an adult or adolescent in the immediate household, most often a parent, grandparent, older sibling, boarder, or household employee.[42] Casual extrafamilial contact is the source of infection much less often, but physicians, babysitters, schoolteachers, music teachers, school bus drivers, parishioners, nurses, gardeners, and candy store keepers have been implicated in individual cases and in hundreds of mini-epidemics.* Attention has been drawn to the prevalence of active tuberculosis among residents of nursing homes for the elderly.[286] Children visiting their grandparents have contracted tuberculosis in this setting. Within the household of an infectious adult, infants and toddlers most often become infected. Adults with pulmonary disease who are receiving regular, appropriate chemotherapy probably rarely infect children; much more dangerous are those with chronic tuberculous disease that is unrecognized, inadequately treated, or in relapse because of the development of resistance.

*References 26, 67, 179, 351, 359, 696.

Wallgren[689] was the first to point out that children with tuberculosis rarely infect other children. Many children with the disease have tuberculin-negative siblings and parents. Children with tuberculosis often have been cared for by their families or in hospitals and institutions without infecting their contacts.[131,445] When transmission of *M. tuberculosis* has been documented in children's hospitals, it almost invariably has come from an adult with undiagnosed pulmonary tuberculosis.[27,305,306,434,698] Adults accompanying a child with suspected tuberculosis disease should be screened as soon as possible for pulmonary tuberculosis.* In tuberculous children, tubercle bacilli in endobronchial secretions are relatively sparse and cough is not characteristic of endothoracic tuberculosis or miliary disease. When young children cough, they lack the tussive force of adults. Specimens collected by bronchoalveolar lavage or early-morning gastric aspiration from children with clinically suspected tuberculosis seldom have acid-fast bacilli seen on smears. Only approximately 40 percent eventually will grow *M. tuberculosis* by culture.[602] Young infants with congenital tuberculosis or advanced, postnatally acquired pulmonary disease are more likely to have smear- or culture-positive specimens (80%) than older children.[545,670] Therefore, specimens and secretions from infants, children with cavitary lesions, and intubated patients should be handled as potentially infectious.[100,406] Most preadolescent children with tuberculosis, however, are not contagious and do not require isolation. Tuberculosis in adolescents may be more typical of adult-type reactivation disease, including the presence of cavitary lesions with smear- and culture-positive sputum. Children or adolescents who have symptomatic pulmonary tuberculosis with features of adult-type tuberculosis should be treated as potentially contagious until mycobacterial smears and cultures are negative.[81,136]

Children, nonetheless, play an extremely important role in the transmission of tuberculosis, not so much because they are likely to contaminate their immediate environment but rather because they may harbor a partially healed infection that lies dormant, only to be reactivated as infectious pulmonary tuberculosis many years later under the social, emotional, and physiologic stresses arising during adolescence, pregnancy, or old age. Thus, children infected with *M. tuberculosis* constitute a long-lasting reservoir of tuberculosis in the population. From an epidemiologic perspective, the diagnosis of tuberculosis disease in a child is a marker of recent transmission in the community, owing to the short incubation periods seen for childhood tuberculosis.

The risk for infection developing in child contacts of adults receiving antituberculosis chemotherapy often is a matter of practical concern. Several studies reveal that most contacts are infected by the index case before the diagnosis is made and treatment is initiated. Although it is not possible to carry out a definitive clinical study, evidence indicates that patients receiving effective chemotherapy rarely transmit *M. tuberculosis*. Nonetheless, it seems prudent to avoid exposure of children to adults with positive sputum smears or positive cultures and to

*References 70, 100, 118, 131, 307, 308, 445, 614.

assume that adults positive by smear or culture remain infectious for at least several weeks after the start of therapy.

MYCOBACTERIOLOGY

The genus *Mycobacterium*, closely related by its cell wall antigens to the genera *Corynebacterium* and *Nocardia*, is classified in the order Actinomycetales and the family Mycobacteriaceae. Several species are termed *M. tuberculosis* complex (MTBC): *M. tuberculosis*, *M. africanum*, *M. bovis*, *M. canetti*, and *M. microti*. Phylogenetic analysis indicates an origin for MTBC approximately 40,000 years ago, coinciding with expansion of humans out of eastern Africa.[706]

Mycobacteria are nonmotile, non-spore-forming, pleomorphic, weakly gram-positive rods measuring 1 to 5 μm long and typically slender and slightly "bent." Some appear beaded, and some are clumped. In general, species pathogenic for humans are more acid fast, have more exacting nutritional requirements, grow more slowly, form less pigment, and are more sensitive to chemotherapeutic agents than are the saprophytic species. The cell wall constituents of mycobacteria determine their most striking biologic properties. The cell walls contain 20 to 60 percent lipids by dry weight, largely bound to proteins and carbohydrates. These organisms are more resistant than are most others to light, alkali, acid, and the bactericidal action of antibodies. Their growth is slow, with a generation time of 14 to 24 hours, perhaps because of the slow metabolic exchange through the waxy "capsule." Their hydrophobic properties render them difficult to study.

Acid-fastness, that is, the capacity to form stable mycolate complexes with certain aryl methane dyes (specifically, carbolfuchsin, crystal violet, auramine, and rhodamine, which then are not removed readily even by rinsing with 95 percent ethanol plus hydrochloric acid), is the hallmark of mycobacteria. The cells appear red when stained with fuchsin (as with the Ziehl-Neelsen or Kinyoun stains), appear purple with crystal violet, or exhibit yellow-green fluorescence under ultraviolet light (when stained with auramine and rhodamine, as in Truant stain). Truant stain, in experienced hands, is considered the best stain for specimens expected to contain small numbers of organisms. Fluorescent staining can decrease staining time by 50 percent and increase sensitivity capacity in high-volume laboratories in developing countries when compared with Ziehl-Neelsen staining.[352] One study of LED fluorescence microscopy in adults showed that fluorescence microscopy was more sensitive but less specific than Ziehl-Neelsen staining, in part because in the fluorescence microscopy artifacts can fluoresce, leading to false-positive results.[134]

Identification of mycobacteria depends on their staining properties and on their biochemical and metabolic characteristics. Mycobacteria are obligate aerobes. On the whole, their growth requirements are simple. *M. tuberculosis* can grow in "classic" media, whose essential ingredients are egg yolk and glycerin (Löwenstein-Jensen, Petragnani, Dorset); often, a dye such as malachite green to inhibit contaminants; and, sometimes, potatoes and charcoal, which probably neutralize growth inhibitors. They also can grow in simple synthetic media, frequently with an admixture of asparagine, glutamate, or amino acid mixtures (Middlebrook 7H9, Tween-albumin). Once grown, they can be replated on media also containing antituberculosis drugs to determine drug susceptibility patterns. Isolation on solid media often takes 3 to 6 weeks, followed by another 2 to 4 weeks for drug susceptibility results. Improvements in laboratory methods have permitted more rapid culture, identification, and drug susceptibility testing of mycobacteria, such as by an automatic radiometric method known as the BACTEC method, in which a decontaminated, concentrated specimen is inoculated into a bottle of medium containing carbon 14–labeled palmitic acid as the substrate.[581] As mycobacteria metabolize the carbon 14–labeled palmitic acid, carbon dioxide 14 accumulates in the head space of the bottle, where radioactivity can be measured. Unfortunately, cross-contamination of bottles has been reported and has resulted in false-positive culture results.[178] The addition of appropriate dilutions of antituberculosis drugs permits an evaluation of drug susceptibility to be made. The time for identification and drug susceptibility testing can be reduced to 1 to 3 weeks, depending on the size of the inoculum.

Restriction fragment length polymorphism (RFLP) analysis and whole-genome analysis of mycobacterial DNA have become powerful tools for determining strain relatedness in both outbreaks and routine epidemiology of tuberculosis in a community, allowing for social network analysis.[9,211,586,710] Bacteriophage typing is of comparably limited utility compared with RFLP and other sequencing modalities.

RESISTANCE AND IMMUNITY

Natural resistance to tuberculosis infection varies greatly among animal species; humans, guinea pigs, and rabbits are highly susceptible. However, Lurie[376] experimentally bred resistant rabbits and showed that although the tubercle bacilli disseminated just as well in the resistant rabbits, multiplication within tissues was inhibited. Thus, the differences between resistant and susceptible rabbits appeared to lie in the ability of the resistant rabbits to produce an effective immune response, and this ability seemed to be controlled genetically. Multiple single nucleotide polymorphisms (SNPs) have been associated with disease susceptibility in a number of racial and ethnic groups: CCL2-2518G in Asians and Latinos,[201] *IRGM*[323] and interleukin-12B in African-Americans, and P2X7 and Toll-like receptor 2 and 8 mutations in Turkish children.[138,139,646] However, few mutations, apart from *SLC11A1*,[356,384] have been identified that appear to increase susceptibility across racial and ethnic groups. Many of these mutations are in genes influencing macrophage-mediated destruction of the bacillus.[323,646]

Additional evidence that genetic factors influence susceptibility comes from data involving twins. Kallmann and Reisner[300] noted that when one homozygous twin suffered from tuberculosis, the other twin had a higher

chance of being affected than was the case with heterozygous twins. Gender affects resistance, and females appear to be especially susceptible during adolescence. The negative nitrogen and calcium balance that can arise during adolescence may account in part for susceptibility at this age.[298]

Likewise, young age appears to predispose one to tuberculosis.[451,544,670] However, one cannot be sure that the apparent susceptibility is not due to a larger dose of bacteria because of more intimate contact between very young children and their infectors. Diabetes mellitus is a risk factor for progression from infection to disease, with escalating risk associated with worsening glycemic control.[697] Many viral infections depress tuberculin reactivity, but only measles and perhaps influenza have been incriminated in lowering resistance to tuberculosis.[44,246,729] Unfortunately, natural resistance is ill defined and poorly understood.

Cell-mediated immunity is regarded as most important in host defense against *M. tuberculosis*.[169,355] The T cell–mediated immune response involves a variety of cell subsets that are involved in numerous functions, including protection, delayed hypersensitivity, cytolysis, and establishment of memory immunity.[476] The functions also involve an array of cytokines, several of which direct cells of the monocyte-macrophage axis to contain and destroy the invading bacilli.[15,637] The exact role of individual cytokines is not yet clear, but an emerging concept is that much of the clinical response to the presence of *M. tuberculosis* is determined by the balance of the cellular-cytokine response,[169] which to some degree is under genetic influence.[476] In general, T-helper 1 (Th1) responses are more beneficial to the host than are Th2 responses, in part owing to the former's role in activating macrophages in granulomas.[169] Unfortunately, infants and young children have increased propensity to develop Th2 responses to mycobacterial immunogens.[355] Although different strains of *M. tuberculosis* can evoke different host immune responses, there is no apparent association between the genotype and the phenotype expressed in children with disease.[401]

More details about the immune response to *M. tuberculosis* are emerging as new immunotherapies are developed. During the past decade, several monoclonal antibodies directed against tumor necrosis factor–α have been used to manage inflammatory bowel disease and rheumatologic disorders. Unfortunately, use of these agents, particularly infliximab, has been associated with up to a 25-fold increased risk for tuberculosis disease.[601] All immunocompromised patients, including those who will undergo any form of immunotherapy, should be evaluated carefully for tuberculosis infection or disease.

PATHOGENESIS

Portal of Entry

The tubercle bacillus usually is inhaled. The observations of Riley[524] suggest that a single tubercle bacillus can initiate infection. Ghon, Kuedlich, and their associates (Table 96-2) reported that the primary focus found in 2114 autopsies on children was the lung in 95.93 percent of cases. Especially significant is that their study was done at a time when bovine tuberculosis, which might have produced many primary gastrointestinal foci, was much more common than it is today. Ingestion probably accounts for a small percentage of primary pulmonary foci and for some gastrointestinal foci, particularly in infants who have consumed milk containing bovine tubercle bacilli. *M. tuberculosis* has also been transmitted by organ transplantation.[101] Contamination of marijuana bongs has been associated both with clusters of pulmonary tuberculosis[444] and uvulitis.[229] Contamination of a superficial skin or mucous membrane lesion, such as an abrasion of the sole of the foot or the elbow, insect bite, ritual circumcision, or infection of the vulva, may lead to infection. Infection by inoculation with a sputum-contaminated syringe has been reported in more recent years.[252] True congenital infection, although rare, may be a result of either lymphohematogenous spread in the mother during pregnancy or smoldering endometritis.[672]

Incubation Period

The incubation period from the time that the tubercle bacillus enters the body until cutaneous sensitivity develops has been found to be 3 weeks to 3 months.[395] With both bacille Calmette-Guérin (BCG) and experimental infections, the incubation period is shorter when the inoculum is large, and clinical experience suggests that the same is true in humans. Debré, for example, noted long ago that tuberculosis acquired by an infant from its mother was likely to be much more severe than was an infection acquired from a visitor to the home.[148] Animal experiments support this concept. The end of the incubation period coincides with the onset of tuberculin hypersensitivity and may be accompanied by a period lasting 1 to 3 weeks that Wallgren called fever of onset or fever of invasion. At this time, the tissue reaction intensifies throughout the primary complex and may permit the complex to be visible on radiographs.

The "Timetable" of Tuberculosis

Wallgren's tremendous experience with tuberculous children in institutions permitted him to recognize and to describe the usual early course and timing of the initial infection and each of its best-known complications.[692]

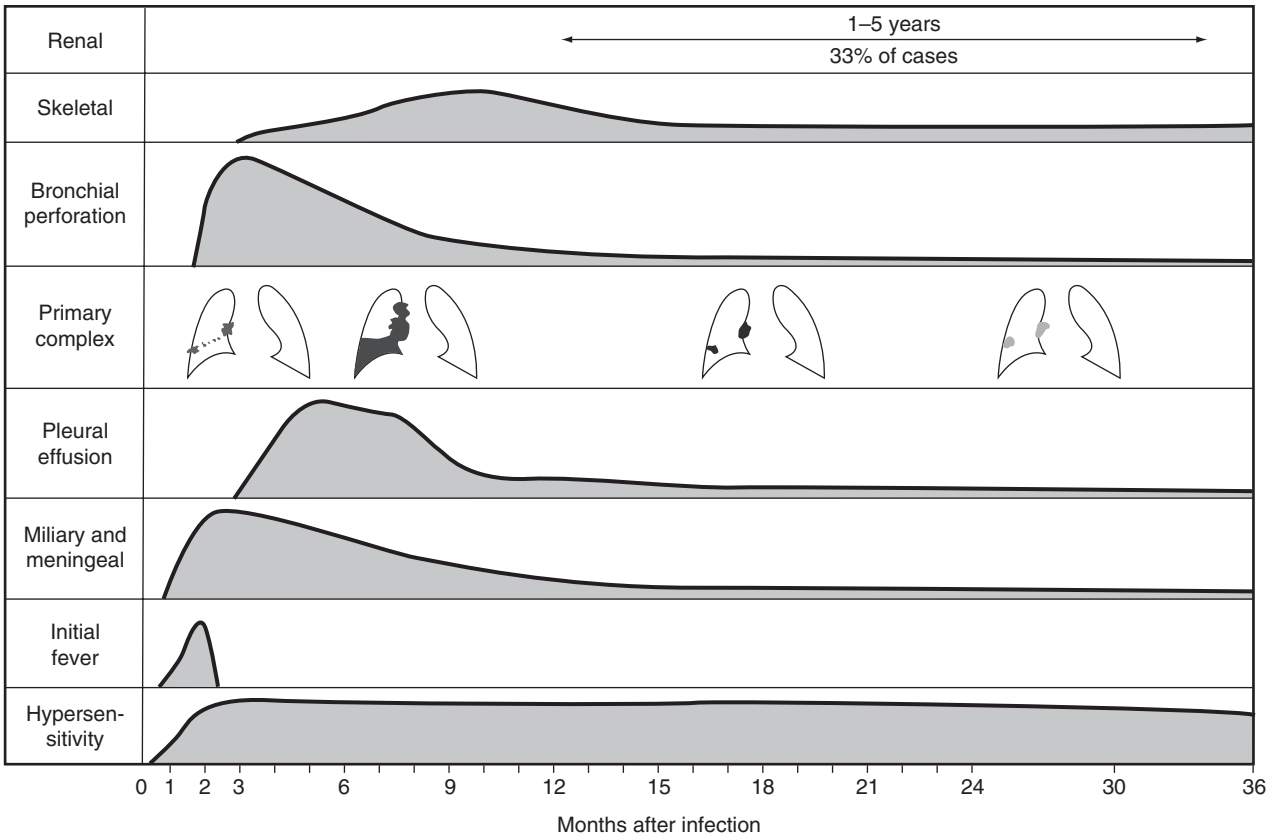

FIGURE 96-5 ■ The timetable of tuberculosis.

His timetable concept is an extremely useful one for clinicians because it permits a realistic prognosis, an understanding of what complications to look for and when, and a more productive approach to finding the infectious source case (Fig. 96-5).[395] Of young adults who progressed from infection to disease, 45 percent developed symptoms within 1 year, 62 percent within 2 years, and 83 percent within 5 years of contact with a source case.[64] One Peruvian study followed contacts of patients with MDR and XDR tuberculosis and showed that 2.6 percent had disease at the time of the contact investigation and that 6 percent developed disease during the 4-year follow-up. The frequency of disease was almost twice as high in contacts of XDR-TB versus MDR-TB patients.[39]

Symptomatic, massive lymphohematogenous spread (i.e., miliary or acute meningeal tuberculosis) is seen in only 0.5 to 3 percent of infected children. When it does occur, the usual onset is 2 to 6 months after initial infection. Endobronchial tuberculosis, possibly with segmental pulmonary lesions, develops slightly later on average. The metastatic lesions of bones and joints, which can be expected in 5 percent of untreated infected children, usually do not appear until approximately 1 year after infection occurs, at the earliest. Renal lesions come later still, 5 to 25 years after initial infection. The relationship between the anatomic site of tuberculosis and the median age at onset in children is shown in Table 96-3. The interval between the acquisition of initial infection and the appearance of chronic pulmonary tuberculosis is extremely variable but can be months to decades, depending mainly on the age of the child at the time of infection. The interval is likely to be short in adolescents but much longer in infants.

In summary, the first 5 years after initial acquisition of tuberculosis infection in childhood, especially the first year, is when complications usually occur. Later in life, during times of stress, a previously silent or arrested lesion may reactivate and become dangerous to the patient as well as highly infectious to others.

CLINICAL FORMS OF TUBERCULOSIS IN CHILDREN

Endothoracic

Asymptomatic Tuberculosis Infection

Asymptomatic (or latent) infection can be defined as infection associated with tuberculin hypersensitivity and a positive tuberculin test result but with no striking clinical or radiographic manifestations. Computed tomography (CT) may reveal enlarged lymph nodes in the chest, even though the plain radiograph is normal.[18,150] On occasion, low-grade fever is found at the onset, usually by chance. If the child has been in recent contact with a person who has contagious tuberculosis and the tuberculin test result is positive, disease should be ruled out immediately with a chest radiograph and a thorough physical examination. Asymptomatic tuberculosis infection occurs more frequently in children of elementary school age than in adolescents or infants. Forty to 50 percent of infections in infants younger than 1 year and 80 to 95 percent of infections in older children can be expected to cause no specific recognizable symptom or radiographic findings.[491] Gastric washings in these patients, even when performed with great care, yield a very low percentage of positive results.

A clinician making a diagnosis of tuberculosis infection in a child must assume, however, that the patient might be in the earliest stage of infection and at risk for the development of symptomatic disease in the near future.[395] A careful history and investigation of contacts should be undertaken immediately for determination, if possible, of the date of exposure. Chemotherapy must be started, and the patient closely monitored not only to detect any toxic effect of chemotherapy and to monitor adherence with treatment but also to be sure that disease does not develop.

The Endothoracic Primary Complex and Its Complications

The primary complex, described by Ghon,[213] includes three elements: the primary focus, lymphangitis, and regional lymphadenitis. This complex holds true for every primary infection, regardless of the portal of entry. Ghon noted that at least 70 percent of primary pulmonary foci are subpleural. Thus, pleurisy is almost a regular feature of the primary complex.

Evolution of the primary pulmonary focus begins with an acute inflammatory reaction around tubercle bacilli inhaled into an alveolus, with the localized alveolar consolidation varying from the size of a pea to the size of a walnut. Macrophages appear within hours in the inflammatory exudate and change into clusters of epithelioid cells to form tubercles. In turn, these tubercles may resolve and disappear or central caseation consisting of incomplete cell autolysis may develop. The caseous lesion contains large numbers of multiplying tubercle bacilli that spread rapidly from the primary focus through the regional lymphatic vessels to the regional lymph nodes, with areas of inflammation being set up along the way that later may caseate and calcify.[502]

TABLE 96-4 **Location of the Primary Pulmonary Focus**

Location	No. of Patients	%
Right upper lobe	138	27
Right middle lobe	40	7
Right lower lobe	107	20
Left upper lobe	122	24
Left lower lobe	104	20
Total	*511*	*98*

Data from Ghon A, Kuedlich H. Die Eintrittspforten der Infektion. In: Engel S, Pirquet C, editors. *Handbuch der Kindertuberkulose.* Stuttgart: Georg Thieme; 1930.

The primary pulmonary focus has been studied carefully by numerous investigators (Table 96-4). Plotting their locations on a normal chest radiograph creates a pattern resembling the scatter of birdshot on a paper target. Thus, all parts of the lung apparently are at equal risk for being seeded. The thought that the primary focus has a predilection for the lower fields of the lung probably arises from the fact that the lung is pyramid shaped, with more basilar than apical lung tissue.

Many investigators concur that 70 to 85 percent of primary infections are initiated by one focus.[123,639] In a study of 170 cases, Ghon[213] found two foci in 15 percent, three in 7 percent, four in 3 percent, and five in 2 percent. Multiple lung foci can result, although rarely, from the ingestion and inhalation of tubercle bacilli. This pattern of disease was shown clearly in the results of pathologic studies of the 71 infants who died in the Lübeck disaster of the 1930s, an incident in which 251 neonates mistakenly had been given live tubercle bacilli by mouth instead of BCG vaccine. Fifteen of the neonates were found to have primary lung lesions at autopsy, and all 251 had primary intestinal lesions.

Although the lymphadenitis cannot be detected clinically and rarely is apparent even on radiographs, the hallmark of initial tuberculosis infection is the relatively large size and importance of the adenitis as opposed to the relatively insignificant size of the initial focus in the lung, skin, or elsewhere. The development of tuberculin hypersensitivity within 3 to 12 weeks after initial acquisition of infection enhances the cellular reaction throughout the primary complex, but with a particularly prominent effect on the primary focus and the regional lymph nodes. At this time, the infection may spread along nearby lymphatic chains to involve more distant nodes. The lymphatic drainage of the lungs is outlined in Table 96-5; it occurs predominantly from left to right. One is not surprised, therefore, that the nodes in the right upper paratracheal area appear to be the ones most often affected. Many primary lesions are subpleural, and the lymphatic drainage of the apical pleura is to the cervical nodes. Moreover, the paratracheal chains have communications with both the deep cervical nodes and the abdominal nodes, as shown in Figure 96-6.

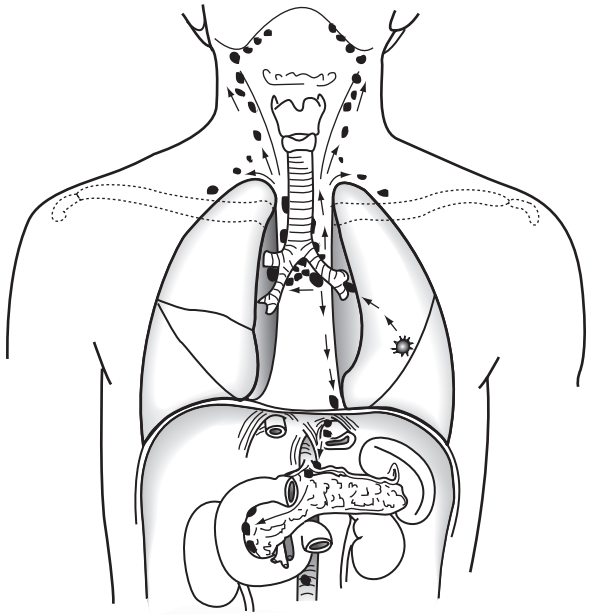

FIGURE 96-6 ■ Schematic composite drawing illustrating wide lymphogenic spread of the tuberculosis infection from a primary pulmonary focus in the base of the left upper lobe. The infection extended cephalad to the submandibular nodes in the head and caudad as far as the pancreatic nodes in the abdomen. (From Caffey J. *Pediatric x-ray diagnosis*. 7th ed. Chicago: Year Book; 1978.)

Bronchial obstruction as a result of enlargement of the peribronchial lymph nodes was reported by Ghon[188] and others. Not until the 1920s did Wallgren[690] and others elucidate the role of these large nodes in producing the radiographic shadows variously called epituberculosis, collapse-consolidation, and segmental lesions that so often are seen in cases of childhood tuberculosis.[362,394,690] At the end of the incubation period, as tuberculin sensitivity develops, the hilar lymph nodes enlarge greatly and, in many cases, caseous foci appear within them. Acid-fast studies of smears and sections have confirmed that this caseum has few tubercle bacilli. As the nodes enlarge, they frequently impinge on the neighboring regional bronchus and compress it and cause diffuse inflammation of its wall, even to the point of obstructing the lumen.[362,557,608] Daly and colleagues,[141] in their study of endobronchial tuberculosis in children at Bellevue, found this mechanism to be the cause of obstruction in half their patients. Other mechanisms of obstruction include damage to the bronchial cartilage leading to gradual (or, rarely, abrupt) perforation of the bronchus and the formation of plugs of semiliquid toothpaste-like caseum that partially or completely occludes the bronchus. In some cases, endobronchial granulomatous tissue forms around the stoma of the fistula and obstructs the lumen.

Three immediate results of bronchial obstruction are possible. The first is sudden death by asphyxia, fortunately an extremely rare event.[343]

The second possible result is obstructive hyperaeration (also called *obstructive emphysema*) of a lobar segment, a lobe, or even an entire lung. This unusual result usually affects children younger than 2 years old, and it may be accompanied by wheezing. Physical examination generally is of little help; radiographs, best taken on expiration, show hyperaeration, which usually is not accompanied by mediastinal displacement, probably because of fixation by the tuberculous mediastinal nodes (Fig. 96-7). Aspiration of a foreign body always must be considered in the differential diagnosis. The obstruction ultimately resolves by itself; however, corticosteroids may be added to the chemotherapeutic regimen to hasten recovery.[452,453,660] Surgical removal of the obstructing nodes has been successful but rarely is performed.[147]

The third possible result of bronchial obstruction is the appearance of a segmental lesion that is fan shaped on a radiograph, representing mainly atelectasis and almost always involving the very segment occupied by the primary pulmonary focus[339,394,437] (Fig. 96-8). Actually, the radiographic opacity results from a combination of several elements: the primary pulmonary focus, the caseous material from an eroded bronchus, the inflammatory response elicited by the caseum, and atelectasis. In some instances, acute secondary infection plays a role. Children with secondary bacterial pneumonia often initially have high fever, cough, and rales; the signs and symptoms respond to conventional antibiotics, but the chest radiographic findings usually do not clear because of the underlying tuberculosis. The relative roles of these various elements often cannot be assessed; sometimes atelectasis is conspicuous, and at other times consolidation is the salient pathologic process, with the volume of the segment undiminished or even increased (hence the descriptive term *collapse-consolidation lesion*, preferred by some clinicians to the less accurate term *atelectasis*).

The percentage of infected children in whom segmental lesions develop has been estimated by several investigators. All agree that the younger the child, the more frequently collapse-consolidation lesions occur (Table 96-6). The segmental lesion is likely to form during the first 3 to 6 months after acquisition of infection (50 of 65 in Payne's series[491]). Multiple segmental lesions can occur simultaneously (18 of 160 children in Payne's experience). When multiple lesions develop, the segmental lesions usually form in one lung, but occasionally the lobes or segments of both lungs are affected. Sometimes, segmental lesions and obstructive hyperaeration occur simultaneously. The physical signs and symptoms of segmental lesions—cough, rales, localized wheezing,

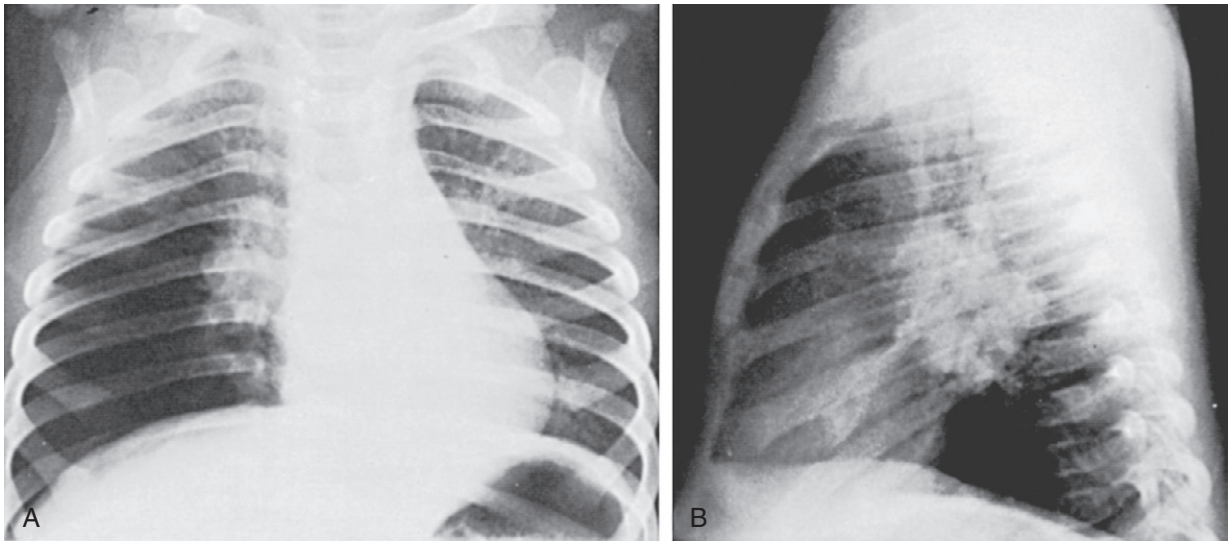

FIGURE 96-7 ■ Radiograph of an 8-month-old girl with obstructive hyperaeration of the right lower lobe as a result of tuberculosis. **A,** Note the hyperlucent right lower lobe and shift of the heart and mediastinum away from the ball-valve obstruction to the left. **B,** Note the large hilar lymph nodes that are compressing the right lower lobe bronchi. Tuberculosis should be considered in patients with hyperaeration of unknown cause.

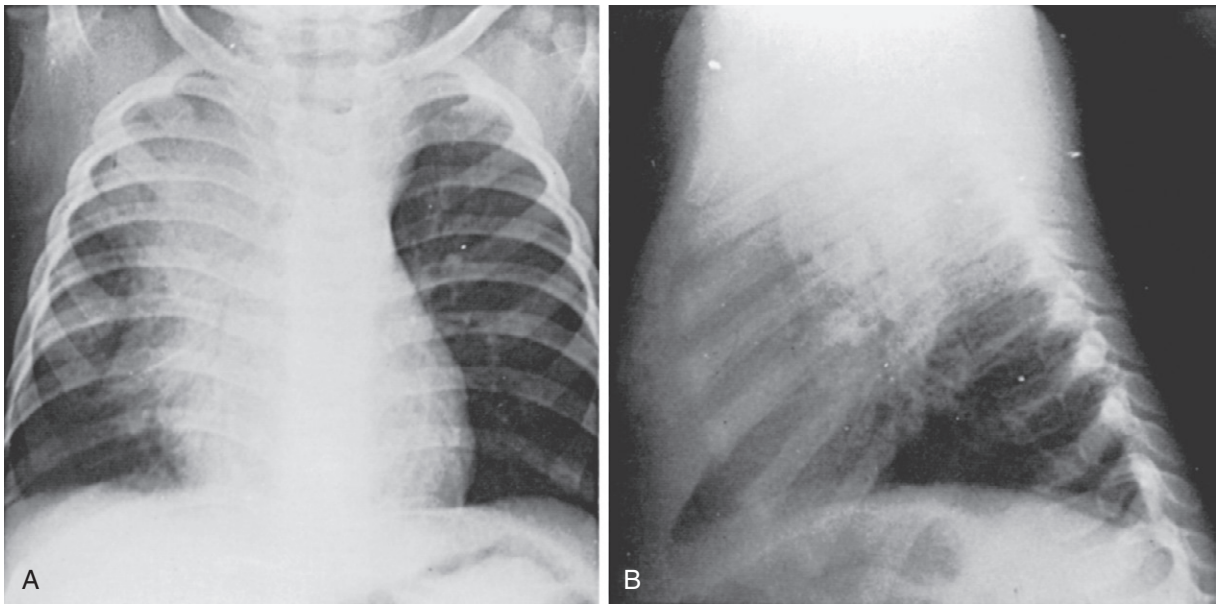

FIGURE 96-8 ■ **A** and **B,** Radiographs of an 8-month-old boy with primary tuberculosis. The posteroanterior film shows collapse-consolidation of the right upper lobe, hilar and paratracheal adenopathy, and pleural reaction. Note the narrowed right bronchi.

egophony—are surprisingly meager but are seen more frequently in infants because of the smaller size of their airways.

Although segmental lesions and hyperaeration are the most common findings produced by enlarging thoracic lymph nodes, others occur. Enlarged peritracheal nodes may cause stridor and respiratory distress.[391] Subcarinal nodes may impinge on the esophagus and cause difficulty swallowing, followed occasionally by the formation of an esophageal diverticulum, or the nodes may rupture directly into the esophagus and produce a bronchoesophageal fistula. Enlarged lymph nodes may compress the subclavian vein and produce edema of the hand and arm, or they may erode major blood vessels, including the aorta. They also may rupture into the mediastinum and point in the left or more often the right supraclavicular fossa. Compression of the left recurrent laryngeal nerve has been reported. Compression of the left phrenic nerve leads to paralysis of the left leaf of the diaphragm in an estimated 0.1 to 0.3 percent of tuberculous children. Rupture into the pericardial sac is described later.

The late results of bronchial obstruction include the following possibilities: complete reexpansion of the lung and resolution of the radiographic findings; disappearance of the segmental lesion, with residual calcification of the primary focus or the regional lymph nodes; or

scarring and progressive contraction of the lobe or segment, usually associated with bronchiectasis.[362,395] Permanent anatomic sequelae result from segmental lesions in approximately 60 percent of all cases, even though the abnormality usually is not apparent on plain radiographs. Cylindrical (rarely saccular) bronchiectasis, sometimes stenoses, and elongation or shortening can be demonstrated on bronchography. Fortunately, most of these abnormalities are asymptomatic in the upper lobes. However, secondary infection may occur in the middle and lower lobes and cause the middle lobe syndrome.[72] On occasion, the chronic vascularity that accompanies bronchiectasis leads to poor oxygen saturation during exercise and to restricted body growth. In addition, bronchogenic carcinoma may arise years later in the old scarred lesions remaining in the bronchus.

Calcification of the primary complex, when it appears, always results from caseation. In calcified caseum, as in bone, the predominant calcium salt is tribasic calcium phosphate. Calcification of caseous lesions occurs much more readily in children than in adults, probably because children's calcium and phosphorus plasma levels are higher. In the infants who were victims of the Lübeck disaster, autopsy showed calcification to be present as early as 58 days after the onset of massive infection. Payne,[491] in a study of calcification in 299 children from Newcastle-on-Tyne, reported calcification visible on the chest radiographs of one child within 6 months of infection and in 38 within 12 months, 104 within 18 months, 165 within 24 months, 252 within 3 years, and all 299 within 4 years.

Calcium usually is deposited as fine particles and creates a stippled effect (Fig. 96-9), but it may be deposited in large, even enormous masses. Calcification may persist without much change, or it may start resorbing within 5 years and eventually disappear completely. It occasionally progresses to ossification with the formation of true bone and functional bone marrow. Calcification, if it is visible at all on radiographs, most often involves the regional lymph nodes.[68] Sometimes, however, the primary pulmonary focus or the entire primary complex, including the lymphangitis, calcifies (Fig. 96-10).

Calcification took place in 75 to 80 percent of the 525 children with pulmonary tuberculosis monitored by Payne.[491] Currently, extensive calcification occurs uncommonly in the Western world, probably because tuberculous lesions treated early with isoniazid rarely caseate and caseation is a prerequisite for calcification.

Pleural Effusion

Pleural effusion can be localized or generalized and unilateral or bilateral.[360] The majority of children will have concomitant pulmonary parenchymal disease and/or intrathoracic lymphadenopathy.[132] All tuberculous serous effusions probably originate in the discharge of bacilli into the cavity from an adjacent lesion—in the case of the pleura, from a subpleural pulmonary focus or from subpleural caseous lymph nodes. The breakthrough may be small and the pleuritis localized and asymptomatic, or it may occur in the form of a generalized effusion, usually 3 to 6 months after infection occurs (Fig. 96-11). In 75 percent of Wallgren's[690] cases, later calcification of the pulmonary focus or regional lymph nodes proved the effusion to be on the same side as the original primary focus. Seemingly without logical explanation are the following clinical observations: tuberculous pleural effusion is a rare occurrence in children younger than 2 years and an uncommon one in children younger than 5 years (perhaps because sensitivity to tuberculin is lower in the very young), occurs more frequently in boys than in girls, almost never is associated with a segmental lesion, and rarely is associated with miliary tuberculosis.

The onset of pleurisy usually is abrupt and resembles bacterial pneumonia, with fever, chest pain, shortness of breath, and, on physical examination, dullness to percussion and diminished breath sounds. Fever may be high and, in untreated cases, last for several weeks. On occasion, differentiation of an effusion from an extensive pneumonic lesion is difficult; lateral decubitus radiographic views are helpful in confirming the presence of pleural fluid.

Thoracentesis is, of course, the essential diagnostic procedure. The puncture should be made in the area shown on the radiograph to have the greatest accumulation of fluid. No more than 30 mL of pleural fluid should be withdrawn; otherwise, the protein loss from this usually protein-rich fluid may be considerable. The fluid generally is greenish yellow, occasionally tinged with blood, with a specific gravity of 1.012 to 1.022, a high protein content, and often a low glucose level (<30 mg/dL), and it has several hundred white cells per cubic millimeter with a predominance of neutrophils or lymphocytes, depending on the age of the effusion. Polymerase chain reaction (PCR), adenosine deaminase levels of 38 IU/L, and absolute lymphocyte count of greater than or equal to 275 cells/mm^3 in pleural fluid had a sensitivity and specificity of 74 percent and 88 percent, 81 percent and 75 percent, and 90 percent and 83 percent, respectively, in one study of children with tuberculous effusions.[426] The cells in tuberculous pleural effusion are predominantly T lymphocytes, which are present in a higher proportion than in blood.[193,577] Tubercle bacilli generally are present in such small numbers that results from direct smears and cultures are likely to be disappointing; smears almost always are negative, and pleural fluid cultures are positive in less than 30 percent of cases.

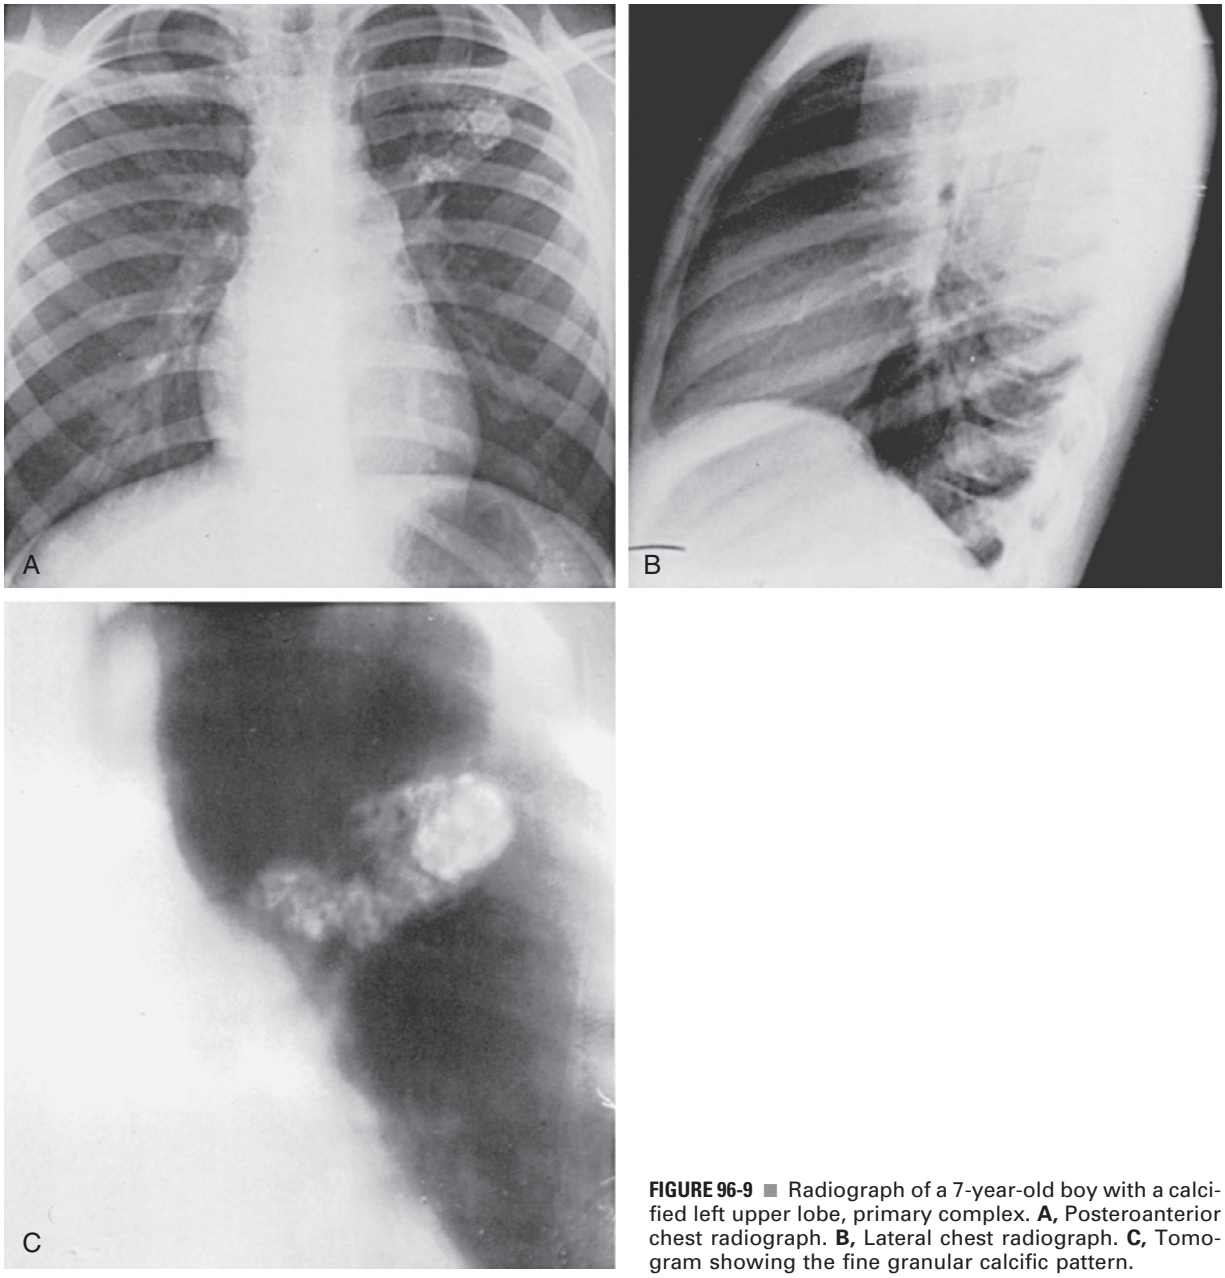

FIGURE 96-9 ■ Radiograph of a 7-year-old boy with a calcified left upper lobe, primary complex. **A,** Posteroanterior chest radiograph. **B,** Lateral chest radiograph. **C,** Tomogram showing the fine granular calcific pattern.

Pleural biopsy is a useful diagnostic procedure because both the finding of typical tubercles on histologic study and culture of the tissue are much more likely to establish the diagnosis than is culture of pleural fluid.[354]

The prognosis for children with tuberculous effusion always has been relatively good compared with that for other overt forms of tuberculosis, even in the days before chemotherapy.[364] Clinical improvement occurs well before radiographic resolution of disease, and the majority of children have radiographic abnormalities at the completion of therapy.[132] Permanent impairment of pulmonary function is a surprisingly uncommon event after pleural effusion.[204] The development of scoliosis is a remote possibility and should be guarded against while the patient recovers.

Progressive Pulmonary Tuberculosis

In this serious complication of the primary complex, the primary pulmonary focus, instead of resolving or calcifying, enlarges steadily and develops a large caseous center. This center then liquefies and empties into an adjacent bronchus to create a "primary cavity"[644,677] (Fig. 96-12); the liquefaction is associated with particularly large numbers of tubercle bacilli. The tubercle bacilli further disseminate to other parts of the lobe and to the entire lung, where other foci of infection form. On rare occasion, an enlarging primary focus ruptures into the pleural cavity and creates a pneumothorax, bronchopleural fistula, or caseous pyopneumothorax or ruptures into the pericardial sac or the mediastinum.

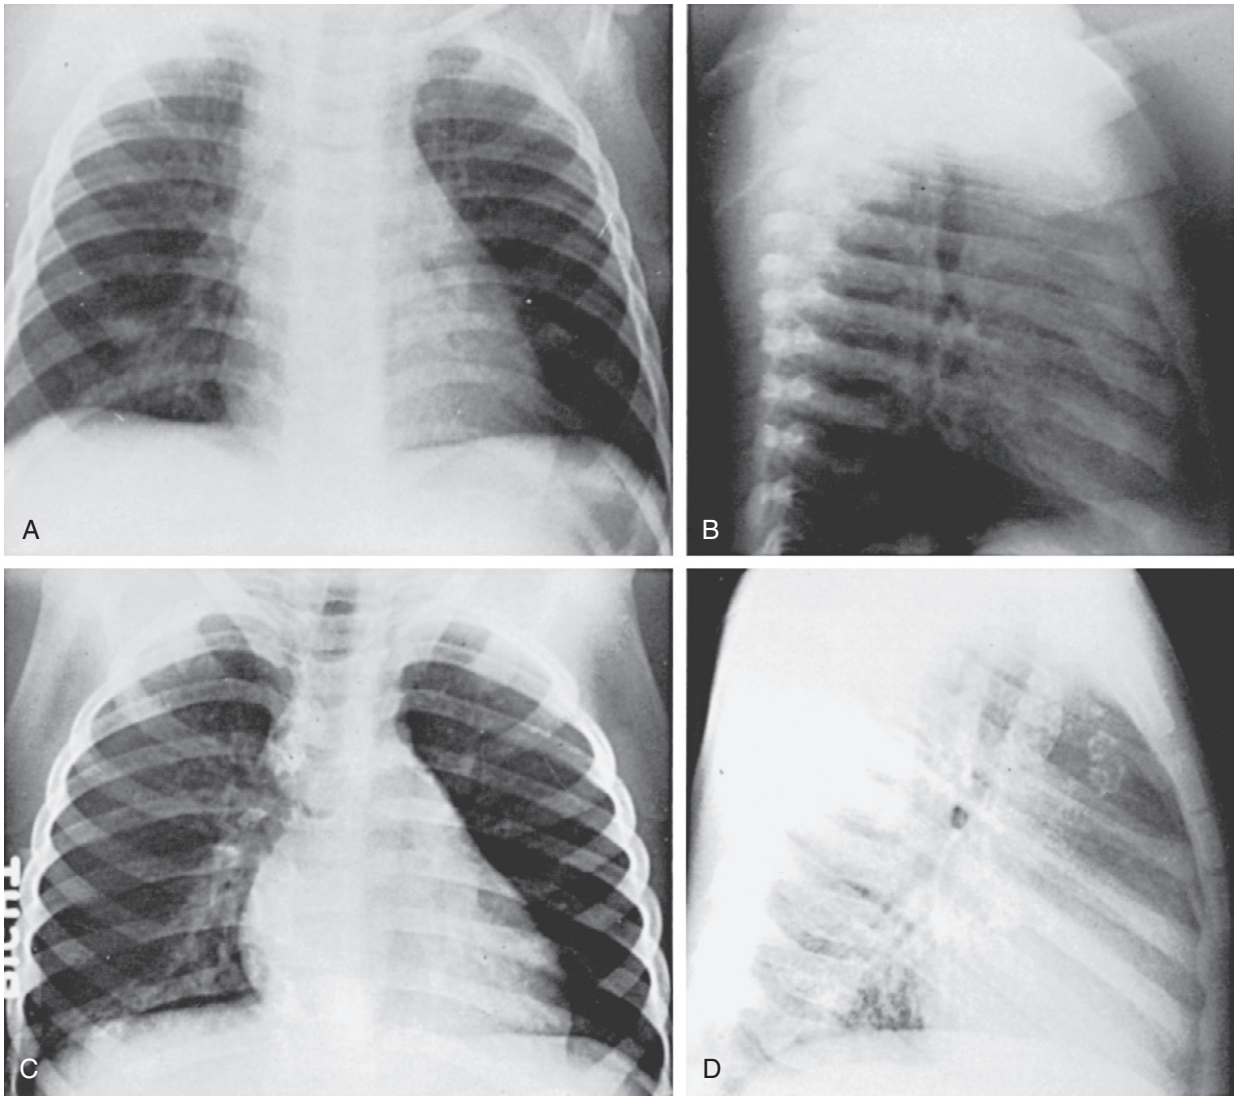

FIGURE 96-10 ■ **A** and **B,** Radiographs of a 7-month-old girl with mild fullness of the right upper mediastinum and a hazy infiltrate in the right lower lobe. The result of a skin test for tuberculosis was positive. She was treated for tuberculosis and clinically improved. **C,** The same patient 3.5 years later has a calcified primary complex in the right upper and lower lobes over the diaphragm. **D,** The anterior location of the upper lobe complex is seen clearly on the lateral chest radiograph.

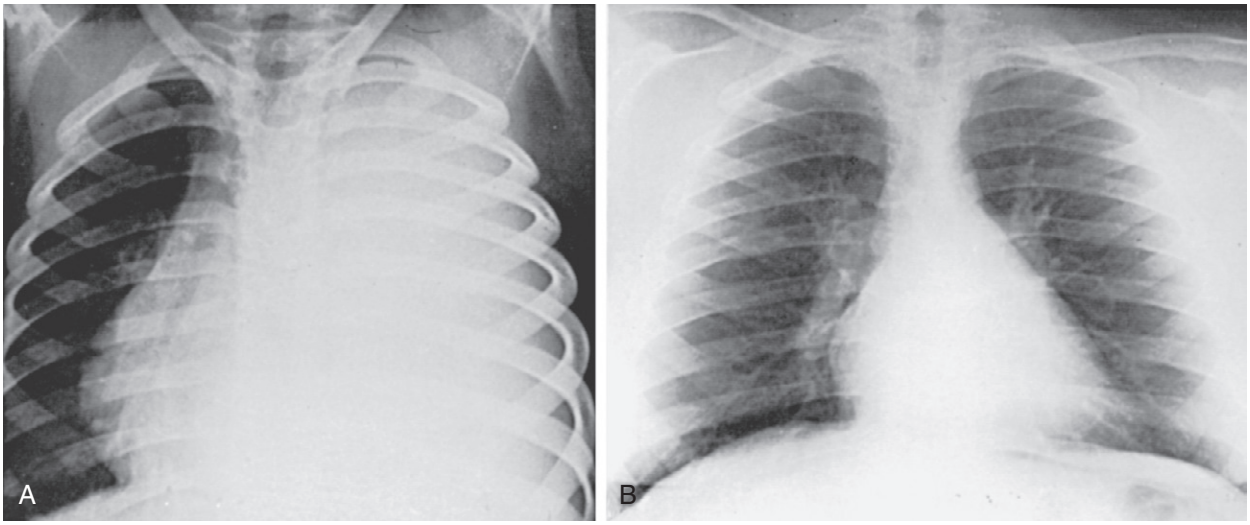

FIGURE 96-11 ■ **A,** Posteroanterior chest radiograph of a 5-year-old boy with massive left pleural effusion caused by tuberculosis. **B,** Normal radiograph 6 years later from the same patient who had no physical complaint.

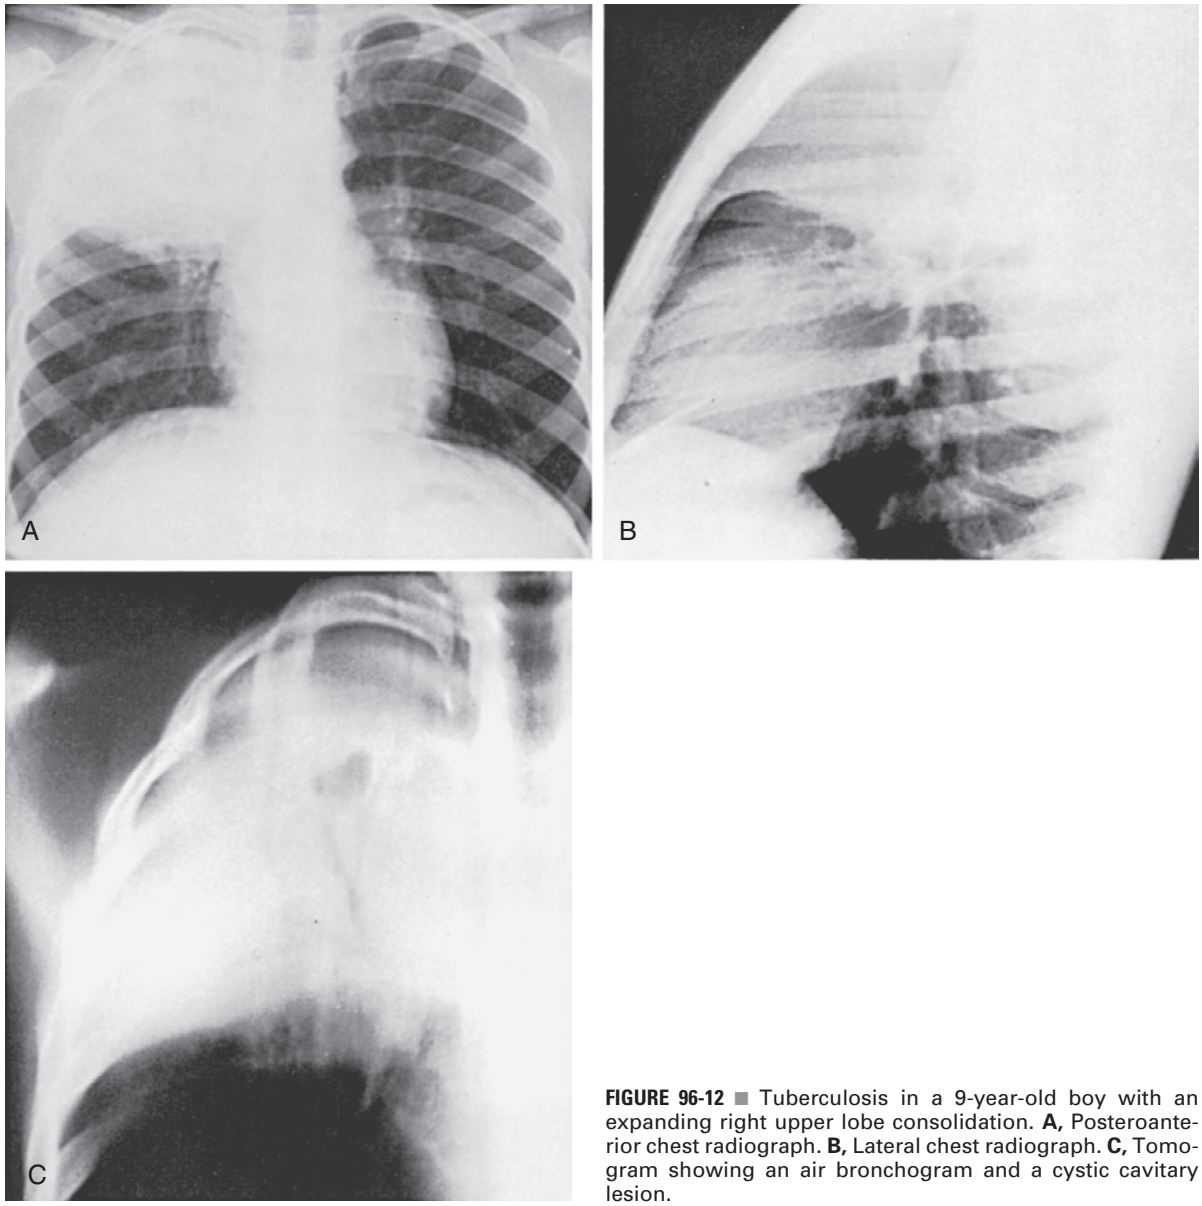

FIGURE 96-12 ■ Tuberculosis in a 9-year-old boy with an expanding right upper lobe consolidation. **A,** Posteroanterior chest radiograph. **B,** Lateral chest radiograph. **C,** Tomogram showing an air bronchogram and a cystic cavitary lesion.

Although clinical symptoms often are minimal when the primary focus is uncomplicated, a progressive lesion often is accompanied by more severe fever, cough, malaise, and weight loss as well as classic signs of cavitation, such as egophony.[227,545] Before chemotherapy was available, the inability to contain the primary focus was associated with a grave outlook; 25 to 65 percent of patients thus affected died. Now, with appropriate treatment, the prognosis is good.

Distinguishing between progressive pulmonary tuberculosis and a simple tuberculous focus with a superimposed acute bacterial pneumonia caused by *Staphylococcus*, *Klebsiella*, or anaerobes may be difficult. Antimicrobial agents effective against these pathogens may be indicated, in addition to appropriate antituberculosis drugs. Sometimes, especially during convalescence from pulmonary parenchymal lesions, bullous lesions appear and persist for several months. They seem to be associated, in children as in adults, either with "tears" in damaged alveolar walls or with the emptying of caseum out of cavities.[407]

Chronic Pulmonary Tuberculosis

Chronic pulmonary tuberculosis, sometimes referred to as adult or reactivation tuberculosis, is the type of disease seen in pulmonary tissue sensitized and immunized by an earlier tuberculosis infection. For many years, ongoing debate centered on whether the lesions of chronic pulmonary tuberculosis, more localized than those of the initial tuberculous lesion and less likely to spread to lymph nodes and the bloodstream, were due to "endogenous reinfection." Evidence that has accumulated during subsequent decades indicates that endogenous reinfection is the usual event.[619] However, reinfection with a different strain of *M. tuberculosis* has been documented and may be more common in areas where tuberculosis is prevalent.[587]

Careful long-term studies of children have revealed a continuum of involvement in many cases: first the primary focus, followed within a few years in some patients by infraclavicular small round foci in the lung apices that often were calcified (Assmann foci, Simon foci) and thought to result from hematogenous spread at the time of initial infection. Later, these foci disappear spontaneously or remain visible as tiny calcifications or as larger "round foci," which may, if untreated, progress to the typical lesions of chronic pulmonary tuberculosis.

Even before antituberculosis drugs were discovered, chronic pulmonary tuberculosis was a rare occurrence in children (e.g., 6% to 7% in the series of Lincoln and colleagues[361] of closely monitored patients at Bellevue Hospital). It appears more frequently in children in the lower socioeconomic strata of society and more frequently in girls than in boys. Chronic pulmonary tuberculosis rarely develops in children who survive with a healed, untreated tuberculosis infection acquired before they have reached 2 years of age, but it is much more frequent in children who acquire their initial infection after reaching 7 years of age and particularly if they become infected close to the onset of puberty. In that case, the "adult" type of lesion often develops in the very lobe where the primary lesion occurred. In this situation, progressive pulmonary tuberculosis cannot be differentiated from chronic pulmonary tuberculosis. Now, with effective treatment, such differentiation is unimportant.[240]

Cough, fever of unknown origin, chest pain, hemoptysis, and supraclavicular adenitis are the most common clinical manifestations. Essential diagnostic procedures are the tuberculin skin test and appropriate chest radiographs, often including such special procedures as tomograms and lordotic views. An intense search for tubercle bacilli must be made in sputum, gastric washings, and, if necessary, secretions obtained by bronchoscopy.

Myocardial and Pericardial Tuberculosis

Tubercles often are found in the heart in miliary tuberculosis. Although it is exceedingly rare, myocardial caseation has been described that is usually secondary to direct spread from mediastinal glands and accompanied by paroxysmal tachycardia or arrhythmias.[691]

Tuberculous pericarditis, although more common than symptomatic tuberculous myocarditis, occurred in only 0.4 percent of 2500 children monitored by Lincoln and Sewell[364] at Bellevue Hospital and in 4 percent of 200 children in Boyd's series.[66] It occurs more commonly in males than in females. In most cases, tuberculous pericarditis probably arises by direct invasion or by lymphatic drainage from caseous lymph nodes in the subcarinal area or from nodes close to the ductus arteriosus, with resulting exudation of hemorrhagic fluid and the development of granulation tissue on both the parietal and visceral surfaces of the pericardium. Pericardial fluid may be serofibrinous or hemorrhagic; tubercle bacilli rarely are found on smears.[273] Sometimes, extensive fibrosis leads to obliteration of the pericardial sac, with the development, usually years later, of constrictive pericarditis.

The initial symptoms generally are nonspecific: low-grade fever, poor appetite, failure to gain weight, and, rarely, chest pain. On examination, a pericardial friction rub may be heard, or if a large effusion already is present, distant heart sounds, tachycardia, and a narrow pulse pressure may suggest the diagnosis. The diagnosis then is confirmed by radiography, echocardiography, electrocardiography, tuberculin skin test, and aspiration of fluid for culture. Before the advent of chemotherapy, approximately half the patients succumbed. Now, with appropriate drugs and possibly corticosteroids to diminish the size of the effusion[633] and also occasional partial pericardiectomy, the outlook is excellent.

Lymphohematogenous Spread

Tubercle bacilli from the lymphadenitis of the primary complex are disseminated during the incubation period in all cases of tuberculosis infection. The results of liver biopsy of young asymptomatic tuberculin converters (indicating recent infection) show that the liver always is involved.[117] Tubercle bacilli can reach deep, distant organs through the bloodstream or lymphatic channels. Autopsies on individuals who have died soon after development of initial infection show that bacilli often are deposited in the liver, spleen, skin, and apical pulmonary tissue.

The clinical picture produced by lymphohematogenous spread probably is determined by host susceptibility at the time of spread and by the quantity of tubercle bacilli released.[574,679] Three clinical forms can be recognized:

1. The lymphohematogenous spread may be occult, in which case it usually remains so, or it may be occult initially with metastatic, extrapulmonary lesions appearing months or years later (e.g., renal tuberculosis).[521]
2. So-called protracted hematogenous tuberculosis, rarely seen today, is characterized by high, spiking fever, marked leukocytosis, hepatomegaly and splenomegaly, and general glandular enlargement, sometimes with repeated evidence of metastatic seeding in the choroid, kidneys, and skin. Calcifications may appear subsequently, often in large numbers, in the pulmonary apices (Simon foci) and in the spleen, thus attesting to the earlier dissemination of tubercle bacilli through blood. The tuberculin skin test result usually is strongly positive. Bone marrow biopsy may confirm the clinical impression, but treatment often must be started on a presumptive basis.[527] Although this type of tuberculosis in past years often ended tragically in tuberculous meningitis, today it is completely treatable if it is diagnosed in time.
3. The third form of lymphohematogenous spread, analogous to sepsis with pyogenic bacteria, is miliary tuberculosis.[275,574] It usually arises from discharge of a caseous focus, often a lymph node, into a blood vessel such as a pulmonary vein; it may be self-propagating, with repeated discharge arising at various sites. Most common during the first 2 to 6 months after infection in infancy, it can arise even in adults who have apparently well-healed, calcified lesions.[321,556]

Miliary disease provides a striking illustration of the difference in susceptibility of tissue to tubercle bacilli; tubercles tend to be larger and more numerous in the lung, spleen, liver, and bone marrow than in the heart, pancreas, and brain. The number of fixed intravascular phagocytes, as well as the relative tortuosity of the smaller blood vessels themselves, must play an important role in determining tissue susceptibility. In acute caseating miliary tuberculosis, the lesions are likely to be numerous and sometimes almost coalescent.

The clinical picture of miliary tuberculosis varies greatly, probably depending on the number of bacilli in the bloodstream. Sometimes, the patient is afebrile and appears to be well, and the condition is diagnosed by chance during contact investigation of another individual with infectious tuberculosis. The onset can be insidious, often occurring after the patient has had another precipitating infection. In rare cases, the onset is abrupt. Drowsiness, loss of weight and appetite, persistent fever, weakness, rapid breathing with a rustling sound on auscultation of the lungs, occasionally cyanosis, and almost always a palpable spleen are the clinical manifestations that lead the clinician to obtain a chest radiograph.

Usually within no more than 3 weeks after the onset of symptoms, tubercles, sometimes tiny and at times large, can be seen evenly distributed throughout both lung fields[473]; in the early stages, they often are detected best on a lateral view of the retrocardiac space (Fig. 96-13). The incidence of choroidal tubercles varies greatly; it has been reported variously as 13 and 87 percent. Recurrent pneumothorax, subcutaneous emphysema, pneumomediastinum, and pleural effusion are less serious but well-recognized complications of miliary tuberculosis. Second attacks have been reported.[716] Cutaneous lesions, including painful nodules, papulonecrotic tuberculids, and purpuric lesions, may appear in crops.[314]

The diagnosis usually is established by means of the clinical picture and a chest radiograph. Sometimes it is confirmed by a liver or skin biopsy; by culture of *M. tuberculosis* from the gastric aspirate, urine, or bone marrow[117,245]; or by fiberoptic bronchoscopy and transbronchial biopsy.[74] Treatment usually is successful.

Extrathoracic Spread

Central Nervous System Tuberculosis

Tubercle bacilli are distributed by the bloodstream into all parts of the central nervous system (CNS) during lymphohematogenous spread.[363,613] Surprisingly, they do not multiply as well in nervous tissue as in other areas such as the lung. Thus, CNS tuberculosis, although an early manifestation of infection, usually does not appear simultaneously with miliary spread but days later. The tubercle bacilli can affect the CNS in various ways[668,686] and produce tuberculous meningitis,[278,636] serous meningitis,[358,668] tuberculoma,[661,668] or tuberculous brain abscess, or it can affect mainly the spinal cord and cause spinal tuberculous leptomeningitis.[465]

Tuberculous meningitis arises from caseous foci, often very small ones, situated in the brain or meninges.[522] These lesions arise from hematogenous spread early in the infection.[165,290] In time, the caseous foci discharge tubercle bacilli directly into the subarachnoid space. The thick, gelatinous exudate lies in the meshes of the pia-arachnoid in the brain, where it infiltrates the walls of meningeal arteries and veins and produces inflammation, caseation, and obstruction; the exudate can extend along

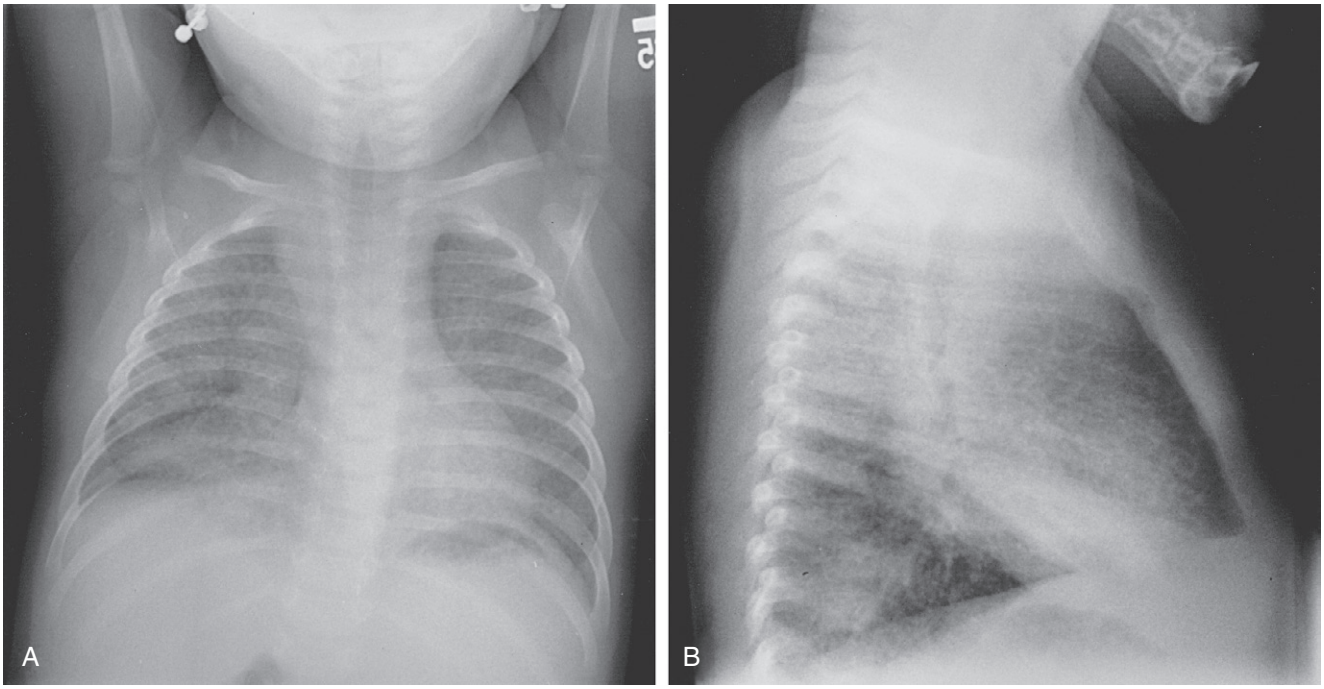

FIGURE 96-13 ■ Miliary tuberculosis in an infant. The numerous tubercles can be seen on both the posteroanterior **(A)** and lateral **(B)** views.

small vessels into the cortex, where it causes occlusion and produces infarcts. This same exudate interferes with normal flow of cerebrospinal fluid (CSF) in and out of the ventricular system and with absorption of the fluid by the pacchionian bodies. The predilection of the exudate for the base of the brain accounts for the frequent involvement of the third, sixth, and seventh nerves and the optic chiasm. The combination of vascular lesions producing infarcts,[353] interference with CSF flow resulting in hydrocephalus, and direct cranial nerve involvement, especially of the eye, causes the devastating damage that all too often results from tuberculous meningitis.[22]

Tuberculous meningitis has been estimated to develop in 1 of every 300 untreated infections.[289] Virtually never seen in infants younger than 4 months, it occurs most frequently in children younger than 6 years, usually appears within 2 to 6 months after initial infection, and accompanies miliary tuberculosis in approximately 50 percent of cases. Tuberculosis should be suspected as the cause of meningitis that is accompanied by cranial nerve involvement, hydrocephalus, or evidence of inflammation at the base of the brain.[673]

The onset of tuberculous meningitis usually is gradual and occurs during a period of approximately 3 weeks; in some cases, it seems to be precipitated by a viral infection, a fall, or a blow on the head. On occasion, the onset is abrupt and marked by a convulsion. A convenient approach is for the clinician to divide the course into three stages. The first stage is characterized by personality change, irritability, anorexia, listlessness, and some fever. After 1 or 2 weeks, the disease passes into the second stage, when signs of increased intracranial pressure and cerebral damage appear: drowsiness, stiff neck, cranial nerve palsies, inequality of the pupils, vomiting, tache cérébrale, absence of the abdominal reflexes, and convulsions that may be tonic or clonic and focal or generalized. The third stage is characterized by coma, irregular pulse and respirations, and rising fever. Papilledema occasionally is noted.

Aids in establishing the diagnosis are a history of contact with an adult who has tuberculosis (however, the family history of tuberculosis often is "negative" because the incubation period of meningitis is short and the contagious adult has not been discovered yet)[159]; a tuberculin skin test (positive result in only 50% of cases); positive tuberculin skin test results in siblings; a chest radiograph, which often reveals pulmonary disease; and changes in, and the characteristic findings from, CSF. However, the ventricular CSF may be relatively normal because it is obtained proximal to the site of inflammation. The lumbar CSF usually is clear and under substantially increased pressure. It will contain 50 to 500 white blood cells/mm^3, with polymorphonuclear leukocytes predominant early and lymphocytes predominant later. The CSF glucose level may be at the lower limits of normal if the patient is examined early in the second stage, and it falls by 5 mg or so each day; by the third stage, it usually is very low. The protein content may be normal at the time of the first spinal tap, but it rises steadily to very high concentrations, at which time a pellicle will develop on the fluid on standing. Tubercle bacilli may be found in the pellicle but are scarce at best. Only approximately 50 percent of cases of tuberculous meningitis in children can be confirmed by culture of CSF. Gastric washings should be cultured, not only to confirm the diagnosis in retrospect but also to permit drug susceptibility testing of the organisms.[723]

CT or magnetic resonance imaging (MRI)[19,22,230,469,707] is recommended for the evaluation of all patients with tuberculous meningitis. Both permit recognition and follow-up of tuberculomas,[667,704] infarction or vasculitis, and hydrocephalus that might require shunting.[22,135,295,627] Involvement of the basal ganglia often is a diagnostic clue for the presence of tuberculosis.[19] Profound abnormalities in the electrolyte pattern of intracellular and extracellular fluid and CSF have been reported in patients with tuberculous meningitis. These abnormalities consist mainly of low sodium and chloride levels, with low or normal plasma potassium levels, accompanied by high sodium levels in red blood cells and skeletal muscle.[241] High levels of antidiuretic hormone (the syndrome of "inappropriate" antidiuretic hormone secretion) may cause hypotonic expansion of the extracellular fluid. Because intense vomiting and dehydration usually accompany tuberculous meningitis, the electrolyte disturbances usually include severe hypochloremia. Salt wasting in the urine occurs in rare cases. Determination of the CSF chloride concentration is useless because it merely reflects the plasma level.

A good prognosis depends on immediate initiation of treatment without awaiting epidemiologic and bacteriologic confirmation of the diagnosis.[274,533] Before chemotherapy was used, every case of true tuberculous meningitis was fatal within 3 to 4 weeks, whereas today appropriate treatment during the first stage allows survival in nearly every case, although the patient's intelligence may never return to its previous level. When it is initiated during the second stage, treatment results in survival in 75 percent or more of patients. If patients are in coma when treatment is begun, they rarely recover unscathed. Very young age and the occurrence of convulsions generally are poor prognostic factors.[533,554] Hydrocephalus, usually of the communicating type, occurs frequently (38% in one series) and is largely responsible for poor outcomes. Relieving the hydrocephalus surgically appears to improve the sensorium, vision, and neurologic deficits. Studies support the early use of ventriculoperitoneal shunting in patients severely ill at the time of admission.[340,482] Infarcts caused by vasculitis also can leave catastrophic residua. The presence of drug-resistant tuberculous meningitis greatly worsens the prognosis,[479] as does coinfection with HIV.[676] The role of corticosteroids in the treatment of intracranial tuberculosis is discussed later in this chapter.

The long-term sequelae of tuberculous meningitis are numerous and include blindness, deafness, intracranial calcification, diabetes insipidus, syndrome of inappropriate antidiuretic hormone secretion, obesity, paraplegia, and mental retardation.[554]

Serous tuberculous meningitis is an uncommon occurrence (13% of 500 cases in the experience of Udani and associates[668]). Apparently, it develops when a tuberculous

focus close to the subarachnoid space causes a lymphocytic reaction in the subarachnoid space without the actual presence of tubercle bacilli.[727] In the days before the advent of chemotherapy, "serous" meningitis was differentiated readily from "true" tuberculous meningitis because the serous type was the only nonfatal form of tuberculous meningitis. Today, such differentiation no longer is possible because treatment is begun immediately, so true tuberculous meningitis does not develop.

Isolated tuberculoma is manifested clinically as a brain tumor.[29,146,160] As many as 30 percent of brain tumors are tuberculomas, depending on the incidence of tuberculosis in the particular population under study (in India, for instance). Tuberculomas occur most often in children younger than 10 years old and often are located at the base of the brain around the cerebellum.[688] In contrast, tuberculomas in adults more often are supratentorial. Headache, convulsions, fever, and other symptoms and signs usually associated with brain abscess or tumor also characterize tuberculoma. Only careful evaluation, including inquiry about exposure to tuberculosis, a tuberculin skin test, chest radiography, and CT, will permit these cases to be recognized in time to begin appropriate chemotherapy before neurosurgical intervention is needed. The widespread use of neuroimaging has revealed that small, multiple tuberculomas are a frequent feature of tuberculous meningitis in infants and young children.[19,22] A phenomenon recognized fairly recently is a symptomatic intracranial tuberculoma appearing and enlarging during treatment of meningeal, miliary, and even pulmonary tuberculosis.[5,350,514,575,650] This phenomenon appears to be mediated immunologically; it usually responds to corticosteroids and does not necessitate a change in antituberculosis chemotherapy. In addition, some small children with severe pulmonary or disseminated tuberculosis have one or several tuberculomas but normal findings on CSF evaluation.[159,291] In one series, HIV-infected children were more likely to have cerebral atrophy and less likely to have intense basal meningeal enhancement than HIV-uninfected children.[149] CT or MRI of the head should be performed whenever neurologic signs or symptoms accompany tuberculosis.

Tuberculous brain abscess is a rarely reported form of CNS tuberculosis that tends to occur at an older age than tuberculoma does.[335,703] On pathologic examination, the lesion lacks the giant cell and granulomatous reaction associated with tuberculoma. Focal neurologic signs occur commonly. CT and MRI, if used routinely in cases of tuberculous meningitis, may permit this type of abscess, which requires surgical intervention as well as chemotherapy, to be recognized more frequently. Intramedullary tuberculoma of the spinal cord is exceedingly rare.[296,378] It can be manifested as recurrent abdominal pain.[51,465]

Spinal tuberculous leptomeningitis occurs more often in older children and adults than in infants[373]; in the series of 500 cases studied by Udani and coworkers,[668] only 2 percent fell into this last age group. Protein levels in the CSF are elevated substantially, and sometimes partial or total block may be noted on myelography. Exudate may completely surround the spinal cord.

Cutaneous Tuberculosis

The manifestations of cutaneous tuberculosis can be classified in children according to a modification of the earlier classifications designed for adults[333]: (1) lesions produced by inoculation from an exogenous source[498] in a previously uninfected child, in a previously infected child, or after inoculation with BCG vaccine; (2) lesions resulting from hematogenous dissemination[314]; (3) lesions arising from an endogenous source; and (4) erythema nodosum. A newer classification has been proposed and perhaps is more useful for adults than for children.[50]

Skin lesions associated with the primary complex may be caused by direct inoculation of tubercle bacilli into a traumatized area, such as a lesion on the sole of a child's bare foot, a mosquito bite on the face, an abraded elbow, or the foreskin at the time of ritual circumcision.[484,563] The initial skin focus usually is a small, painless nodule, sometimes with tiny satellite lesions that soon turn into indolent ulcers without surrounding inflammation. The most striking feature is regional lymphadenitis, which often is what convinces the patient to see a physician. Fever and systemic reactions generally are minimal; low-grade pyogenic infection and cat-scratch fever (*Bartonella* infection) always must be considered in the differential diagnosis. A strongly positive tuberculin skin test result usually is obtained. Needle aspiration and culture may differentiate disease caused by *M. tuberculosis* from that caused by environmental mycobacteria.

Scrofuloderma indicates tuberculosis of the skin overlying a caseous lymph node (most often in the cervical area) that has ruptured to the outside and left either a shallow ulcer or a deep sinus, sometimes surrounded by a cluster of nodules. In the past, scrofuloderma was a frequent manifestation of tuberculosis in children and usually left extensive scars. Today, it is a rare occurrence because the diagnosis generally is made before the node ruptures. Administration of chemotherapy often forestalls the need for surgical excision.

Manifestations that result from hematogenous dissemination are papulonecrotic tuberculids and tuberculosis verrucosa cutis. Papulonecrotic tuberculids[584] are miliary tubercles in the skin that usually appear as tiny papules with "apple jelly" centers, most often on the trunk, thighs, and face. They frequently are similar to papular urticaria or early varicella lesions, or they may be confused with the skin lesions of Letterer-Siwe disease. Skin biopsy provides a reliable diagnosis. Lupus vulgaris is a rare form of chronic, indolent tuberculosis, usually on the face, that often seems to evolve from tuberculids, very rarely at the site of BCG inoculation.

Tuberculosis verrucosa cutis is a condition characterized by large (several centimeters in diameter) papulonecrotic tuberculids. The lesions usually appear on the arms, legs, or buttocks, suggesting that trauma may play some part in their causation. Fungal infection is the main consideration in the differential diagnosis.

Erythema nodosum formerly was a common manifestation of hypersensitivity to tuberculin. It occurs mostly in young teenage girls. Usually beginning with fever and systemic toxicity manifesting soon after initial infection develops, erythema nodosum is characterized by large,

deep, painful, indurated nodules on the shins and sometimes on the thighs, elbows, and forearms. The nodules gradually change from light pink to a bruise-like color. Erythema nodosum is not specific for tuberculosis but also occurs with streptococcal and meningococcal infections, histoplasmosis, coccidioidomycosis, sarcoidosis, drug sensitivity reactions, and perhaps cat-scratch disease. Tuberculin hypersensitivity is pronounced in children with tuberculosis underlying erythema nodosum, and tuberculin skin testing should be performed with caution. These patients may or may not have associated tuberculous lesions, but some clinicians hold that these patients have a greater chance of suffering complications. Skin biopsy reveals only nonspecific changes regardless of cause and, therefore, is useless in establishing the diagnosis. Both fever and nodules clear within 2 or 3 weeks.

Skeletal Tuberculosis

Bone and joint tuberculosis can be expected in 1 to 5 percent of children whose initial infection with tubercle bacilli is untreated. Usually, the tubercle bacilli are disseminated to skeletal structures during lymphohematogenous spread of the initial infection.[35] The disease becomes symptomatic during the first 1 to 3 years after infection occurs. Each of the most frequently involved bones and joints has a characteristic "incubation period" (e.g., 1 month for dactylitis but about 30 months for tuberculosis of the hip). In very young children, blood flow through growing bone is intense; consequently, they suffer from skeletal tuberculosis more often than older children do. The lesion usually starts as an area of endarteritis in the metaphysis of the long bone, where the blood supply is particularly abundant; lesions can be single or multiple.[511,573] Bone infection can be initiated by two other mechanisms, particularly in the vertebrae: (1) direct extension through the lymphatics from a caseous paravertebral lymph node[75] and (2) direct local hematogenous or lymphatic extension from a neighboring bone. As bone is destroyed progressively by pressure necrosis and formation of a cold abscess, a nearby joint may become involved.[512,671,687]

The bones most often affected are the vertebrae.[472] In one study of 1074 patients with the disease, 440 had involvement of the vertebrae; 89, the knee; 81, the hip; and 51, the elbow.[665] The upper extremities and non–weight-bearing bones, such as the skull, clavicle, and mandible, rarely are involved.[244,247] Often a history of trauma is present and may play some part in activation of an underlying lesion or may serve simply to draw attention to the process.

Tuberculous spondylitis, or tuberculosis of the vertebrae, frequently affects the thoracic vertebrae, particularly the 12th one.[255] In one series of 64 cases of spinal tuberculosis in children, the lesions were in the thoracic area in 24 children, in the lumbar area in 19, and in both areas in 13. Cervical involvement is a rare finding.[269] Usually, two vertebrae are involved, but sometimes 3, 4, or even as many as 11 (usually contiguous, but at times with "skips") are affected. The body of the vertebra is affected far more often than the spinous processes or the arch.

The progression of tuberculous spondylitis, as seen on radiographs, is from slight narrowing of the disk space with only minimal disk involvement and slight collapse and "wedging" of the vertebral body; to marked narrowing of the disk space with collapse, wedging of the bodies, and resulting angulation of the spine (gibbus); and to extensive destruction of the bodies with severe kyphosis (Pott disease).

Paravertebral abscess (Pott abscess), retropharyngeal abscess, psoas abscess, and neurologic lesions are serious complications to be expected in 10 to 30 percent of cases of spondylitis. Neurologic complications most often arise from cervical and lumbar vertebral lesions and consist of various degrees of neuroplegia, paraplegia, or even quadriplegia. The complications are caused by inflammation of the spinal cord secondary to a neighboring cold abscess, by caseum or granuloma in the extradural space, or by spinal vessel thrombosis.

The signs and symptoms of spondylitis include "night cries" and restless sleep, a low-grade daily fever, and a peculiar position (e.g., torticollis with cervical lesions) or gait. Findings on physical examination may include marked "guarding" because of dorsal muscle spasm, pain when the back is "pounded," a deformity (e.g., gibbus), or reflex changes (including clonus).[408] On occasion, the presence of referred chest pain leads to discovery of a paravertebral abscess on the chest radiograph. With chemotherapy and, when necessary, surgery, the outlook for both eventual clinical healing and neural recovery is in the range of 80 to 90 percent, although patients may not gain their full expected height.

Tuberculosis of the knee can be divided into several clinical types[254]: effusion into the joint without bone erosion and with little restriction of motion; thickening and fibrosis of the synovial membrane without bone erosion but often with considerable restriction of motion; synovial disease and a bone focus but an intact joint space; and synovial disease with diminished range of motion.[629] Some degree of pain, stiffness, and limping, usually intermittent in milder cases, first calls attention to the problem.

Tuberculosis of the hip, in some series of patients more common than tuberculosis of the knee, should be considered in the differential diagnosis when a child refuses to walk or a limp develops. Today, when the disease still is limited at the time of discovery to the acetabulum or to the head of the femur and no intra-articular disease is present, good mobility of the joint usually can be preserved.

Tuberculous dactylitis (spina ventosa)[237] is the most common form of skeletal tuberculosis in infants. Endarteritis is followed by swelling (often painless), and cystic bone lesions are seen on radiographs. A cold abscess may form and drain spontaneously. The prognosis for recovery without deformity is surprisingly good and was so even before chemotherapy was available.

Tuberculous arthritis is a rare finding in children. Usually monarticular, it involves primarily the weight-bearing joints and only exceptionally the joints of the upper extremities. Bacterial cultures and histologic examination of the synovium establish the diagnosis.[687] Poncet disease is a rare form of rheumatic joint disease associated with tuberculosis; it is an exceedingly rare finding in

children.[140] The diagnosis of skeletal tuberculosis should be considered immediately in any child who is known to have been infected with tubercle bacilli and in whom a bone or joint lesion develops and in any child with a persistent, not otherwise explained bone or joint lesion.[684] The differential diagnosis must include low-grade infections caused by *Staphylococcus*, *Haemophilus influenzae*, *Salmonella*, and *Brucella;* fungal infections; rheumatoid arthritis; malignant disease of bone; eosinophilic granuloma, particularly with skull or pelvic lesions; and osteochondrosis resulting from aseptic necrosis of bone, particularly Legg-Calvé-Perthes disease and tuberculosis of the hip.

Children with bone and joint tuberculosis usually react strongly to tuberculin. Although the number of tubercle bacilli in an active bone lesion is much lower than in a lung lesion, the organisms almost invariably can be recovered on culture, and a great effort to do so should be made by means of aspiration or open biopsy.[226]

Treatment of skeletal tuberculosis includes both chemotherapeutic and orthopedic interventions, with the chemotherapeutic interventions by far the more important.[509] Orthopedic procedures can be used for several purposes: establishment of the diagnosis, evacuation of caseum and necrotic bone, immobilization of a joint, and reconstruction or strengthening of damaged bone. Since the advent of chemotherapy, any indicated surgical procedure can be performed without fear of subsequent development of sinus formation. However, the trend has been toward reliance on drug therapy with increasingly conservative surgical management. Controlled trials of treatment undertaken in different parts of the world (Southeast Asia) by the Medical Research Council Working Party on Tuberculosis of the Spine and others have demonstrated the remarkable effectiveness of ambulatory treatment with different regimens of chemotherapy in children and adults,[280,412-414] including short-course chemotherapy.[235]

Tuberculosis of the Superficial Lymph Nodes (Scrofula)

Striking enlargement of the superficial regional lymph nodes is an integral component of the primary tuberculous complex. The tonsillar and submandibular nodes are involved most often and probably represent extension from the paratracheal lymph nodes (and not from a primary lesion in the tonsil, as once was thought); occasionally, these nodes are involved when the primary lesion occurs in the mucous membranes of the mouth, a rare event. Enlarged supraclavicular nodes may accompany a primary pulmonary lesion in the upper lung fields.[558] Enlarged axillary and epitrochlear nodes can result from a primary skin lesion of the elbow or hand, often a small, insignificant-looking area that has, however, been present for some time. Preauricular adenitis suggests a focus on the scalp or forehead or in the lacrimal sac, sometimes attributed to an insect bite. With inguinal adenitis, careful examination of the sole of the foot may reveal a small ulcer, often at the base of the toes.

When the superficial lymph nodes are involved early in the course of infection—the normal event—the enlargement usually is painless and the node or nodes are rubbery and discrete.[400] Low-grade fever generally is present, sometimes unnoticed by the parents. On occasion, acute respiratory tract infections seem to precipitate or to aggravate superficial tuberculous lymphadenitis and the patient has high fever, some local pain, and perilymphadenitis. Rarely, the patient is seen first with a fluctuant mass and the overlying skin is shiny and erythematous.[143,605]

The diagnosis usually is not obvious, so it is wise in all cases of superficial cervical and supraclavicular lymphadenitis to perform a throat culture, radiography of the chest, and a Mantoux tuberculin test. If the node is fluctuant, it should be aspirated and cultured for mycobacteria as well as for pyogenic bacteria.[344] In preauricular, axillary, and inguinal adenitis, a possible primary skin lesion should be sought diligently. If a lesion is found, a biopsy should be performed, in addition to a tuberculin skin test, chest radiography, and a careful history.

Currently, in addition to pyogenic infection, the following need to be considered as possible causes: cat-scratch disease, tularemia, malignant tumors, sarcoid, and infection caused by mycobacteria other than *M. tuberculosis*.[34,338] If the adenitis is caused by infection with *M. tuberculosis*, the induration from a Mantoux tuberculin skin test usually is greater than 15 mm, whereas mycobacteria other than *M. tuberculosis* produce a less intense reaction. The key to distinguishing tuberculosis from infection by another mycobacterium generally is epidemiologic—has the child been exposed to tuberculosis?

Because infection with pyogenic bacteria often enhances mycobacterial adenitis, frequently a wise approach is to institute therapy with a conventional antibacterial agent while awaiting the results of the skin test, chest radiography, and cultures. If the adenitis persists and evidence of mycobacterial infection is elicited, antituberculosis drug therapy should be initiated and surgical excision seriously considered.[338,557] Surgical excision currently is the treatment of choice for adenitis caused by mycobacteria other than *M. tuberculosis*. In the case of lymphadenitis caused by *M. tuberculosis*, the response to antituberculosis drugs is likely to be good. On the other hand, the adenitis is more likely to extend down into the mediastinum and to be difficult to remove. Under these circumstances, surgical excision probably is unwise, whereas a few weeks of corticosteroid and antituberculosis therapy may be effective.[293,338]

Superficial tuberculous lymphadenitis sometimes occurs early in the course of lymphohematogenous spread, in which case it often is manifested as "general glandular enlargement" accompanied by swinging fever, malaise, and weight loss. The tuberculin test result almost always is positive in immunocompetent patients, and the tuberculin test should be included in the investigation of every patient with general glandular enlargement.

Finally, tuberculous adenitis, either localized or generalized, can occur in adolescents or young adults who were infected months or even years earlier, whose infection has been quiescent, and in whom the appearance of lymphadenitis heralds reactivation of the tuberculosis infection.[337]

Ocular Tuberculosis

Ocular tuberculosis is an uncommon finding in children. When it does occur, the conjunctiva and the cornea are the areas most often involved.[158]

The conjunctiva can serve as the initial portal of entry for tubercle bacilli, especially after trauma. Unilateral lacrimation and reddening may lead to the discovery of yellowish gray nodules, usually on the palpebral conjunctiva. Preauricular adenitis appears early; the submandibular and cervical nodes also may enlarge. A tuberculin skin test and biopsy with culture can be performed to confirm the diagnosis.

Phlyctenular conjunctivitis probably is one of the hypersensitivity phenomena of childhood tuberculosis. Tubercle bacilli have, on rare occasion, been isolated from the small, grayish, jelly-like nodules usually clustered on the limbus and surrounded by dilated conjunctival vessels. Pain and photophobia are intense, and the lesions may recur in crops for weeks and affect one or both eyes. In the differential diagnosis, foreign body, herpes simplex virus conjunctivitis, vernal conjunctivitis, and trachoma should be considered. Tuberculin sensitivity is likely to be pronounced, and 1 tuberculin unit of purified protein derivative (PPD) should be used in the initial tuberculin skin test. Fortunately, hydrocortisone drops are effective in controlling both a strong local reaction to the diagnostic tuberculin test and the discomfort from the underlying disease. The prognosis for complete recovery is excellent, provided the phlyctenules do not ulcerate and leave corneal scars. Systemic chemotherapy should be started immediately after the diagnostic procedures are completed.

Although tuberculosis of the ciliary body and iris has been reported rarely in children, tubercles of the choroid often have been found in patients with miliary tuberculosis (up to 70% of patients in some series) and occasionally in children with a seemingly uncomplicated infection.[438,470] Frequently multiple, the tubercles heal slowly with deposition of retinal pigment; residual scarring apparently can be prevented with corticosteroid therapy. Tuberculous uveitis and tuberculosis manifested as an orbital mass are rare clinical entities.[576]

Tuberculosis of the Middle Ear

Tuberculosis of the middle ear is a relatively rare manifestation of the disease.[194,374,377,443,538] It occurs as a primary focus in the area of the eustachian tube (because of reflux up the tube) in neonates who have aspirated infected amniotic fluid or in older infants who have ingested tuberculous material. It can occur as a metastatic lesion in older children who have a primary focus elsewhere. If it is a primary focus, regional lymphadenitis involves the preauricular lymph node or the anterior cervical chain and facial paralysis occurs frequently. The primary focus always is unilateral. Otorrhea is a common occurrence and painless but may become foul smelling because of bacterial contamination with enteric organisms. Older patients may complain of tinnitus and "funny noises." The eardrum often is damaged extensively. A large central perforation or several perforations are characteristic findings. A tuberculin skin test, biopsy, and careful cultures for tubercle bacilli are essential. Once greatly feared for the almost inevitable loss of hearing and the frequent occurrence of tuberculous meningitis, tuberculous otitis media now heals well with appropriate chemotherapy.[443]

Gastrointestinal and Abdominal Tuberculosis

Tuberculosis of the mouth occurred more commonly in the days of bovine tuberculosis than it does today; at that time, scrofula often represented a primary complex in the mouth or tonsils, with associated submandibular or cervical lymphadenitis.[423] A primary focus in the mouth generally consists of a painless ulcer or mass of granulation tissue around a tooth socket or in the gingivolabial sulcus, with enlarged submental or submandibular nodes. Primary tuberculosis of the tonsils begins as a painless swelling of one tonsil, sometimes with an ulcer or yellowish node and, of course, enlargement of the regional lymph nodes. If tubercles found on histologic examination of a tonsil removed at tonsillectomy are unaccompanied by lymphadenitis, the lesion is considered a metastatic rather than a primary lesion. Tuberculosis of the esophagus occurs rarely if ever in children; sometimes, dysphagia is produced by a mass of mediastinal nodes, which may rupture into the lumen and later heal, possibly leaving an esophageal diverticulum.

Abdominal tuberculosis may occur after the ingestion of tubercle bacilli or as a part of generalized lymphohematogenous spread, but tuberculous enteritis always has been uncommon.[21,52,530,640,643] When tubercle bacilli penetrate the gut wall, they usually do so through the Peyer patches or the appendix, where they give rise to local ulcers followed by mesenteric lymphadenitis and sometimes peritonitis.[20] On occasion, especially in older children, tuberculous enteritis accompanies extensive pulmonary cavitation. Symptoms and signs include vague abdominal pain, intussusception, blood in the stool, and sinus formation after a seemingly routine appendectomy.

The spleen is seeded during the initial lymphohematogenous spread. Only rarely are the tubercles numerous and large enough to undergo caseation and to calcify.[327] The reticuloendothelial system of the liver is involved also. Symptoms rarely are manifested except in miliary tuberculosis, in which the liver may be enlarged markedly, or in congenital tuberculosis, in which both the liver and spleen usually are enlarged.[382]

Mesenteric lymphadenitis can arise as part of an intra-abdominal primary complex or by extension from tuberculous thoracic or pelvic lymph nodes; often asymptomatic, it may be discovered later when calcified. It can cause ascites and dilation of the superficial abdominal veins, but the symptom most frequently attributed to mesenteric lymphadenitis is colicky abdominal pain after exercise, probably because adhesions are stretched.

Tuberculous peritonitis can be a result of direct extension from a primary intestinal focus, adjacent mesenteric lymph nodes, or tuberculous salpingitis.[109,157,212] It may be "plastic" or accompanied by a serous effusion. On palpation, a mass of lymph nodes often can be felt and the abdomen may have a characteristic "doughy" feeling. Paracentesis should be performed with care because the

intestine may be immobilized by adhesions. Even with a large effusion, absorption usually occurs within a month. Malignant disease must, of course, be considered strongly in the differential diagnosis, and it may be necessary to obtain a biopsy specimen even if the tuberculin skin test result is positive. Laparoscopy frequently is useful, as is fine-needle aspiration[367] and ultrasonography.[304] CT is more sensitive for intra-abdominal lymphadenopathy, but less helpful for tuberculous ascites, because it does not detect septations well.[674] The ascitic fluid–blood glucose ratio of the aspirated peritoneal fluid can be helpful in differentiating tuberculous peritonitis from ascites of other causes.[704]

Renal Tuberculosis

Renal tuberculosis is a late and uncommon complication of pulmonary disease; it rarely occurs less than 4 or 5 years after primary infection and is therefore likely to be diagnosed during adolescence.[187,588] However, tubercle bacilli can be recovered from the urine in many cases of miliary tuberculosis and some cases of pulmonary tuberculosis in young children. Hematogenous dissemination can give rise to tubercles in the glomeruli, with resultant caseating and sloughing but tiny lesions, which then discharge tubercle bacilli into the tubules. An encapsulated caseous mass occasionally develops in the zone between the renal pyramid and cortex; it may calcify in situ or discharge into the pelvis of the kidney and form a cavity analogous to a pulmonary cavity. Infection can be unilateral or bilateral and can spread downward to involve the bladder. Frequently, dysuria, hematuria, and "sterile" pyuria are the initial findings in the urine; they may occur grossly but often not until late in the course of a disease that causes strikingly few symptoms. Appropriate examination and culture of single early-morning urine specimens rarely fail to reveal tubercle bacilli. Intensive chemotherapy renders surgical intervention a rare necessity.[588] Urine from patients with renal tuberculosis is highly infectious, and such children should be isolated until their urine is sterile.

Dialysis- and Renal Transplant–Associated Tuberculosis

Infections are a common cause of morbidity and mortality in patients with end-stage renal disease. Depressed cellular immunity, as manifested by cutaneous anergy, delayed homograft rejection, and depressed lymphocyte count, has been demonstrated in uremic patients, whereas cell-mediated immunity appears to recover in stable patients treated by long-term hemodialysis. Thus, it is not surprising that tuberculosis occurs more frequently in patients maintained on dialysis than in the general population and that when it does become active, it does so before or early in the course of dialysis. Extrapulmonary involvement (mediastinal, meningeal, pleural, osseous, and renal) and miliary tuberculosis appear relatively frequently in this group. In these patients, fever of unknown origin should lead to suspicion of active tuberculosis.[16] Tuberculosis also can originate in the transplanted organ.[446,683]

Genital Tuberculosis

Tuberculosis of the genital tract is an uncommon finding in both sexes before puberty.[588] It usually arises as a metastatic lesion during lymphohematogenous spread and occasionally by direct extension from an adjacent lesion of bone, gut, or the urinary tract. Genital tuberculosis is a particular hazard for adolescent girls with tuberculosis infection. Frequently, other forms of tuberculosis associated with initial infection, such as a pleural effusion, also are present. The fallopian tubes are involved in 90 to 100 percent of cases, the endometrium in 50 percent, the ovaries in 20 to 30 percent, and the cervix in 2 to 4 percent.[551] With tubal involvement, peritoneal tuberculosis occurs frequently.

Lower abdominal pain and amenorrhea usually prompt the patient to seek medical care. A lower abdominal mass, free peritoneal fluid, and constitutional symptoms may or may not be present. Chemotherapy is effective, but infertility remains a potential sequela of the disease.

Tuberculosis of the external genitalia has been seen as a manifestation of child abuse.

Genital tuberculosis can occur in males as primary tuberculosis of the penis after ritual circumcision; many such instances were reported in the past.[258,484] Massive inguinal lymphadenopathy in a circumcised infant should arouse suspicion of a possible tuberculous etiology. Epididymitis or epididymo-orchitis can occur in early childhood.[221] These disorders are characterized by nodular, painless swelling of the scrotum and a dragging pain in the groin and have a gradual onset rather than the acute onset that results after trauma, torsion of the testis, mumps orchitis, or epididymitis associated with bacterial infection.

Inoculation Tuberculosis

More than 200 cases of syringe-transmitted tuberculosis have been described in the world literature.[252] It has become more common since the widespread use of injectable penicillin and routine childhood immunization and usually has been a result of contamination of the syringe or the solution by an individual with infectious sputum. If the recipient has not been infected previously, the lesion in the muscle or subcutaneous tissue will be the primary focus and the regional lymph nodes will enlarge, caseate, and, under favorable circumstances, calcify. However, at least 10 infants thus infected have died as a result of generalized tuberculosis and in others bone tuberculosis has developed. If the recipient already is tuberculin positive, a tuberculous abscess will form without regional lymphadenitis. In this case, an injection abscess must be differentiated from a deep tuberculous abscess arising in the stage of hematogenous dissemination.

Perinatal Tuberculosis (Congenital and Postnatal)

Transmission of *M. tuberculosis* from mother to infant through the placenta or amniotic fluid has been reported in approximately 300 patients.[80] Infection of the placenta

has been demonstrated, and tubercle bacilli have been grown from the tissues of stillborn infants and from living infants within a few days of birth. Perinatal tuberculosis can be acquired by the infant through one of several routes:

1. By transplacental spread through the umbilical vein from a mother with primary hematogenous tuberculosis occurring during pregnancy (i.e., true congenital tuberculosis). The liver is enlarged, enlarged lymph nodes may be present at the porta hepatis, and evidence of widespread miliary disease may be seen in the infant (i.e., the infant may have a primary liver complex or primary lung complexes).
2. By in utero aspiration of amniotic fluid infected from endometritis in the mother or from the placenta. This route of infection also constitutes true congenital tuberculosis. In both these situations, clinical onset of signs and symptoms is likely to be rapid (by 2 to 3 weeks of age) and to include failure to thrive, fever, respiratory distress, and hepatosplenomegaly.
3. By ingestion of infected amniotic fluid or secretions during delivery. This mechanism would seem to be less well documented than the first two routes, but it certainly is a possibility.
4. By inhalation of tubercle bacilli at or soon after birth from the mother, other relatives, or attendants with infectious pulmonary tuberculosis. This route is the most common mode of transmission to neonates.
5. By ingestion of infected breast milk or cow's milk.

One cannot always be sure of the type of infection in a particular neonate; only clear-cut evidence of a primary complex in the liver establishes a definite diagnosis of congenital tuberculosis. However, the presence of early forms of tuberculosis (e.g., pleural, miliary, or meningeal) in the mother during pregnancy or the puerperium also is strong evidence of true congenital tuberculosis in the infant.

The last two listed routes are really means of "postnatally" acquired tuberculosis and need, for epidemiologic purposes, to be distinguished from the first three routes. Neonates with these types of tuberculosis usually lack striking clinical features until they are 1 or 2 months of age.

The diagnosis of perinatal tuberculosis is likely to be difficult to establish and often delayed.[349] Disease in the mother often is overlooked; the mother may have pleural effusion, fever of unknown origin, cough, endometritis, and other symptoms without the tuberculous etiology being recognized. The early symptoms and signs in the neonate likewise are overlooked frequently and may be similar to those caused by other congenital infections. Once the diagnosis is suspected, treatment should be started immediately, and diagnostic procedures should be carried out rapidly and aggressively.

The clinical manifestations vary, probably depending on the size of the infecting dose of bacilli and the site and size of the caseous lesions.[409,454] In many of the reported cases, tuberculosis disease was discovered only at autopsy.[272] Symptoms usually appeared during the second week of life and included loss of appetite and failure to gain weight, fever, nasal or ear discharge, cough, bronchopneumonia, jaundice, hepatomegaly, and splenomegaly occurring later.[80] Wasting has been noted frequently and, in one case, clearly was shown to be caused by hypoadrenocorticism.[435]

Because the result of the tuberculin skin test very rarely is positive in infants, demonstration of tubercle bacilli in gastric washings, middle ear fluid, lymph node biopsy specimens, skin biopsy specimens, bone marrow aspirate, endotracheal aspirate, or lung biopsy specimens is essential.[232] Examination of the placenta for organisms or characteristic histopathologic changes can be extremely helpful and should be done when tuberculosis is diagnosed in the mother around the time of delivery. Successful treatment of congenital tuberculosis has been reported by several investigators, although clinical response may be very slow, and extensive calcification of the lungs, liver, spleen, and muscles may result.[309,313,454,594,607]

Tuberculosis in Adolescents

Tuberculosis in adolescents has become relatively more important as the incidence of infection in childhood has lessened.[151,390,593] Logically, it should be considered in two ways: first, tuberculosis acquired as an initial infection during the adolescent years and, second, tuberculosis infection acquired in early life and reactivated during adolescence.[393,456] In actual practice, separating the two often is difficult or impossible, and most clinical reports and studies do not do so.

Tuberculosis in adolescents may occur exactly as it does in young children, or a classic primary complex may progress rapidly to chronic pulmonary tuberculosis while the hilar lymph node involvement characteristic of childhood tuberculosis remains present. The Medical Research Council in 1963 published a report of 504 cases of tuberculosis in adolescents, including 316 cases of pulmonary tuberculosis, 44 cases of pleural effusion, 44 with hilar lymph node enlargement, 6 cases of miliary and 5 of meningeal tuberculosis, 13 with bone and joint disease, and 8 with genitourinary tuberculosis. In a series of cases of primary tuberculosis in adults, Stead[619] included 11 adolescents, 5 with simple primary tuberculosis, 5 with pleurisy and effusion, and 1 with progressive pulmonary tuberculosis.

From the extensive clinical experience of Lincoln and Sewell[364] and others, several observations emerge. Tuberculosis infection in early infancy rarely leads to pulmonary tuberculosis in adolescence, perhaps because it has several years in which to heal, whereas tuberculosis infection acquired after 7 years of age and, in particular, acquired after 10 years of age is likely to progress. When *M. tuberculosis* is acquired during adolescence, chronic pulmonary tuberculosis may develop within 1 to 3 years. Moreover, the risk for acquiring pulmonary tuberculosis is two to six times greater for adolescent girls than for adolescent boys. In both sexes, the adolescent growth spurt is the time of greatest risk. The work of Johnston[298] suggests that the depressant effect of puberty on calcium and nitrogen retention, at least in girls, may be correlated with the failure of tuberculosis infection to heal.

Tuberculosis and Pregnancy

In the era before chemotherapy, whether pregnancy and tuberculosis affected each other adversely was an ongoing controversy. Since the advent of chemotherapy, however, the prognosis has improved greatly.[203] The main problems now are serious unrecognized tuberculosis in a pregnant woman, sometimes with a fatal outcome, and serious unrecognized disease in her infant. Another problem is whether pregnancy influences the risk for progression of tuberculosis infection to disease; the data are conflicting in this regard. Tuberculin skin testing probably is valid during pregnancy; chest radiographs (with shielding) should be obtained for all tuberculin-positive pregnant patients. Therapy, when indicated, can safely include isoniazid (which crosses the placenta but apparently without ill effects), rifampin, and ethambutol. The safety of pyrazinamide in pregnancy has not been established, but a growing number of experts recommend it because anecdotal data have not shown it to be harmful to the mother or fetus. Streptomycin, because of fetal ototoxicity, is not recommended.[599] However, one study of seven pregnant women with multidrug-resistant tuberculosis showed no adverse effects on their neonates when mothers were treated with second-line drugs, including aminoglycosides.[174,578] Should a mother receiving antituberculosis therapy breast-feed? It is probably safe for her to do so because the drugs, although found in milk, are present only in small amounts.[600]

Tuberculosis and Human Immunodeficiency Virus Infection

In adults infected with both HIV and *M. tuberculosis*, the rate of progression from asymptomatic infection to disease is increased greatly.[542] The clinical manifestations of tuberculosis in HIV-infected adults are typical when the $CD4^+$ cell count is higher than 500/mm^3. As the $CD4^+$ cell count falls, manifestations become "atypical." Extrapulmonary foci occur in as many as 60 percent of profoundly immunocompromised patients.[31] Pulmonary cavities are rare findings; lower lobe infiltrates or nodules often accompanied by thoracic adenopathy are common occurrences, especially if the patient's tuberculosis infection is recent. Of course, many patients have a nonreactive tuberculin skin test. Sputum is less likely to be produced or to contain visible acid-fast organisms on stained smears; more invasive procedures, such as bronchoscopy, often are required to isolate *M. tuberculosis* and to rule out other causes of opportunistic lung disease.[397] Malabsorption of antituberculosis drugs in HIV-infected patients can lead to prolonged symptoms and disease.[496]

When tuberculosis develops in HIV-infected children, the clinical features tend to be fairly typical of childhood tuberculosis in immunocompetent children, although the disease often progresses more rapidly and the clinical manifestations are more severe.* Many children have sizeable pulmonary radiographic findings with minimal respiratory signs or symptoms. An increased tendency for extrapulmonary disease may be noted. Nonspecific signs and symptoms,[693] overlap in symptomatology with other opportunistic infections, and higher rates of culture-positive patients with negative radiographs make the diagnosis challenging. Consequently, studies evaluating the utility of symptom-based scoring systems have shown discrepant results.[185,392,494] Establishing the diagnosis can be very difficult; a diligent search for an infectious adult in the child's environment may yield the best clues to the correct diagnosis.[325] Recurrent disease and relapse occur more frequently in HIV-infected children.[549] The prognosis generally is good if tuberculosis disease is not far advanced when the patient is diagnosed and appropriate antituberculosis drugs are available.[251]

Tuberculosis and Immune Reconstitution Inflammatory Syndrome

The introduction of highly active antiretroviral therapy (HAART) into regions where tuberculosis is prevalent has had a profound effect on the epidemiology and clinical expression of both diseases. One manifestation may be immune reconstitution inflammatory syndrome (IRIS). IRIS manifestations can include either worsening of tuberculosis symptoms while on effective therapy (paradoxical IRIS) or new-onset tuberculosis symptoms after initiation of HAART (unmasking IRIS).[417,610] Sometimes it is difficult to tell if a deterioration in the clinical course of a patient with an opportunistic infection who is started on HAART is due to IRIS, poor compliance with treatment for the opportunistic infection, or drug resistance.[345-347] Consensus case definitions were created in 2008 to help differentiate among these diagnostic possibilities. Paradoxical IRIS is defined for patients diagnosed with tuberculosis before starting HAART and who showed an initial response to antituberculous medication. Major criteria include new or enlarging lymph nodes or focal tissue involvement, central nervous system findings, or serositis or new or worsening radiographic findings. Minor criteria include new or worsening constitutional or respiratory symptoms or new or worsening abdominal pain accompanied by peritonitis, organomegaly, or intra-abdominal lymphadenopathy. At least one major or two minor criteria are needed for diagnosis. Unmasking IRIS is defined in patients not receiving tuberculosis treatment when HAART is initiated who then develop tuberculosis with evidence of substantial inflammation (e.g., tuberculous lymphadenitis, pulmonary tuberculosis accompanied by respiratory failure).[417]

Factors suggesting IRIS are temporal association (within 3 months of starting HAART), unusual clinical manifestations, unexpected clinical course, exclusion of alternative explanations, evidence of preceding immune restoration (rise in CD4 lymphocyte count), and fall in HIV viral load. In adults, the risk for developing IRIS in patients with tuberculosis who are started on HAART is greatest if they have extrapulmonary tuberculosis, high initial HIV viral loads and low CD4 lymphocyte counts, and rapid response to HAART.[63,442] One meta-analysis showed that paradoxical IRIS developed in 16 percent of adults with tuberculosis.[442] Although the risk for IRIS is higher when HAART is initiated shortly after antituberculosis medications are begun, most reactions are mild

and the survival benefit in patients receiving HAART outweighs the risk for IRIS.[57,302]

Published reports of IRIS in children have been rare,* although anecdotal evidence from pediatric acquired immune deficiency clinics in Africa suggest it is becoming common as HAART is introduced to more children with HIV infection. One study indicated that IRIS was seen in almost 40 percent of HIV-infected children and was more common in boys than girls and more common in children 5 to 12 years of age and that unmasking IRIS comprised more than three fourths of cases.[475] Other studies have shown lower incidence of IRIS,[506,694] but the finding that IRIS is more common in children with disseminated disease and malnutrition has been documented in multiple studies.[475,694] IRIS in children has been associated with nontuberculous mycobacteria,[506] disseminated viral[506,694] or fungal infections,[475] bacterial pneumonia,[475] and previous BCG vaccination.[331,507,580] The finding that IRIS occurs in children with tuberculosis and HIV infection who receive HAART is not surprising. For decades, so-called paradoxical reactions have been described in HIV-uninfected children with tuberculosis after antituberculosis therapy is started. The most common manifestations are fever, cough, new skin lesions, enlarging lymph nodes in the thorax or neck, and appearance or enlargement of tuberculomas in the brain, with or without accompanying meningitis.[417,475] The risk for unmasking IRIS appears to be highest in the first 3 months after initiation of HAART.[30]

IRIS also can be seen in HIV-uninfected children. One study in HIV-uninfected children showed that unexpected deterioration while on therapy was seen in almost 15 percent of children, most commonly manifest as enlarging intrathoracic lymphadenopathy. In this cohort, IRIS was more common in children with multiple sites of disease and in children whose weight was in the lowest quartile.[652]

The best management of IRIS is unknown. As with paradoxical reactions that cause tissue damage or obstruction, corticosteroids may be beneficial to "quiet" the local immune response, although no randomized clinical trials have been reported. Less severe reactions may respond to nonsteroidal anti-inflammatory drugs. The high frequency of IRIS associated with tuberculosis has led some experts to recommend delay of HAART until appropriate (for drug susceptibility pattern) antituberculosis chemotherapy has been given for at least 2 months.[357] No consensus on this approach has been reached, however, and data from children may indicate that they are more likely to die of complications of HIV than of tuberculosis when they are dually infected.[251]

DIAGNOSIS

In the developing world, the only way that children with tuberculosis disease are discovered is passively, when they have a profound illness that is consistent with a manifestation of tuberculosis. Having an ill adult contact is an obvious clue to establishment of the correct diagnosis. The only available laboratory test usually is an acid-fast smear of sputum, which the child rarely produces. In many regions, chest radiography is not available. To aid in establishing the diagnosis, a variety of scoring systems based on available tests, clinical signs and symptoms, and known exposures have been devised.[422,700] However, no single clinical scoring system has been validated, the sensitivity and specificity of these systems can be very low and lead to both overdiagnosis and underdiagnosis of tuberculosis, differing prevalences of tuberculosis can skew predictive values, and scoring systems perform poorly in HIV-infected children.[317,400,422]

In industrial countries, children with tuberculosis usually are discovered in one of two ways.[172,322,544] Obviously, one way is to consider tuberculosis as the cause of a symptomatic illness.[534] Discovering an adult contact with infectious tuberculosis is an invaluable aid to establishing the diagnosis; the "yield" from a contact investigation usually is higher than that from cultures from the child.[41] Culture from the infectious adult case may yield the only drug susceptibility results for the child because cultures from children with tuberculosis frequently are negative. Children often are the first in the family to be diagnosed with tuberculosis, potentially owing to different thresholds for seeking medical attention for children and adults and more rapid onset of severe manifestations in young children. A negative exposure history does not rule out tuberculosis in a child. The yield of contact investigations is higher for children than adults, owing to the former's more limited social network. Yield of contact investigations may be lower in foreign-born children, whose source cases may still reside in their country of origin.[571] The second way is to discover a child with pulmonary tuberculosis during the contact investigation of an adult with tuberculosis.[402,431,603,631,634] Typically, the affected child has few or no symptoms, but investigation reveals a positive tuberculin skin test result and an abnormal chest radiograph. In some areas of the United States, as many as 50 percent of children with pulmonary tuberculosis are discovered in this manner, before significant symptoms have begun.

The recent use of molecular epidemiology techniques has shown, however, occasional discordance between the isolate from the child and that from the presumed source, meaning that the real source of transmission to the child is undiscovered.[710,719] It is less common to find tuberculosis disease in a U.S.-born child as the result of a community- or school-based tuberculin skin testing program, although foreign-born children with tuberculosis may be found in this manner.[173,493]

Tuberculin Sensitivity and the Skin Test

Sensitization to tuberculin is induced by infection with living tubercle bacilli. Specific tuberculin sensitivity to either *M. tuberculosis* or other mycobacteria can be transferred in humans by injection of lymphocytes from sensitized donors and also by injection of certain purified mycobacterial protein antigens. Sensitization to tuberculin as a result of infection with *M. tuberculosis* tends to persist undiminished for life.[186,236,266]

*References 301, 450, 475, 506, 694, 720.

The time of appearance of sensitivity in animals after infection with *M. tuberculosis* has occurred depends on the number of tubercle bacilli in the infective dose and on the virulence (i.e., the rate of multiplication of the organisms), and such is also likely to be the case in humans.[32] For all practical purposes in humans, tuberculin reactivity seems to appear in 3 to 6 weeks, and occasionally as long as 3 months after initial infection. At first, an inflammatory reaction appears at the site of injection, with predominance of segmented neutrophils, followed by immigration of macrophages and T lymphocytes, until the entire area of induration consists of mononuclear cells. The size of the induration depends on the amount of tuberculoprotein injected and the availability of sensitized T lymphocytes in sufficient number. The size of the induration seems to depend on at least two additional factors: the local behavior of the skin (the disappearance time for wheals of normal saline solution, the so-called Aldrich-McClure test, is accelerated during fever, pregnancy, cachexia, and extreme malnutrition) and the number of actively multiplying tubercle bacilli in the body, which can be demonstrated in animals and probably in humans as well. That still other factors must be involved is clear because 10 to 20 percent of immunocompetent patients with proven tuberculosis are tuberculin negative during initial disease, with tuberculin sensitivity often regained during treatment.[501] Decreased T-lymphocyte blastogenesis has been demonstrated in some cases, and inhibition by B lymphocytes may play a role.

Falsely negative tuberculin skin tests can be seen in a number of circumstances. Temporary desensitization to tuberculin occurs most strikingly during measles and has been studied carefully. Full reactivity diminished during the incubation period and returned within approximately 1 month after appearance of the exanthem.[246] Influenza and administration of influenza and measles vaccines tend to depress sensitivity but rarely suppress it entirely.[330,729] Whether other viral diseases and vaccines regularly are less active in this regard and what the important factors may be are not known.[44] If a temporary desensitizing effect occurs in bacterial infections such as scarlet fever, it probably depends on factors such as hyperthermia and dehydration. Corticosteroids,[65,379,552] HIV infection,[388,513] adrenocorticotropic hormone,[537] nitrogen mustard,[695] and irradiation[142] diminish tuberculin reactivity, perhaps simply by inducing lymphopenia.[616]

False-positive results of tuberculin skin tests also are seen. That degrees of sensitivity to *M. tuberculosis* are induced by nontuberculous mycobacteria also is clear.[233] Previous receipt of BCG vaccine can cause increased reactivity to tuberculin, but the association is weaker than many clinicians suspect.[10,84,372,440,566] Less than 50 percent of infants given BCG vaccination have a reactive tuberculin skin test at 9 to 12 months of age, and the great majority will have a nonreactive skin test by the time they are 5 years of age. Older children and adults who receive BCG vaccination have a reactive skin test and keep it longer, but by 10 to 15 years after vaccination most individuals have lost tuberculin skin test reactivity.[125,420,540] Repeated administration of BCG vaccine can maintain tuberculin reactivity.[279] Repeated tuberculin skin tests in a person sensitized previously by BCG vaccination, infection with *M. tuberculosis*, or probably infection by an environmental mycobacterium may increase the reaction to subsequent tuberculin skin tests (called the booster phenomenon).[48,208,565,657]

The antigens currently used in tuberculin testing are crude extracts consisting of a mixture of many antigens, some species specific, some shared among many species. Standardized, isolated, purified mycobacterial antigens are needed in clinical practice. The major antigen used in tuberculin testing is PPD, obtained from filtrates of heat-killed tubercle bacilli. Batch 49608, prepared by Dr. Florence Seibert in 1939, was designated by the WHO as the international standard tuberculin, the only one to be called PPD-S. All other PPD preparations are referred to simply as PPD or as PPD-T. Each batch must be stabilized with Tween 80 at 5 ppm to minimize adherence to glass and plastic and must be identified by manufacturer and lot number. However, the potency of PPD doses varies from batch to batch. The tuberculin vial should be refrigerated (2° to 8° C) and protected from light.

The Mantoux test is the reference test. A graduated syringe and a 26- or 27-gauge needle are used to inject 0.1 mL of PPD into the most superficial layer of the epidermis of the forearm, which raises an immediate wheal (Fig. 96-14). Under optimal circumstances, the needle should not be withdrawn for a few seconds to minimize leakage. If there is leakage or if the injection was too deep and no wheal is noted, the skin test should be repeated at least 5 cm from the original site. The reference test uses a dose of 5 tuberculin units of PPD-S or 2 units of RT-23. The reading should be made at 48 to 72 hours, with the forearm slightly flexed. Any induration (not erythema) should be measured, preferably with calipers, and the diameter at right angles to the axis of administration recorded in millimeters. Any blistering or ulceration also should be noted. Use of the words "negative" and "positive" should be avoided because interpretation can change as more epidemiologic information becomes known. No study has demonstrated that parents

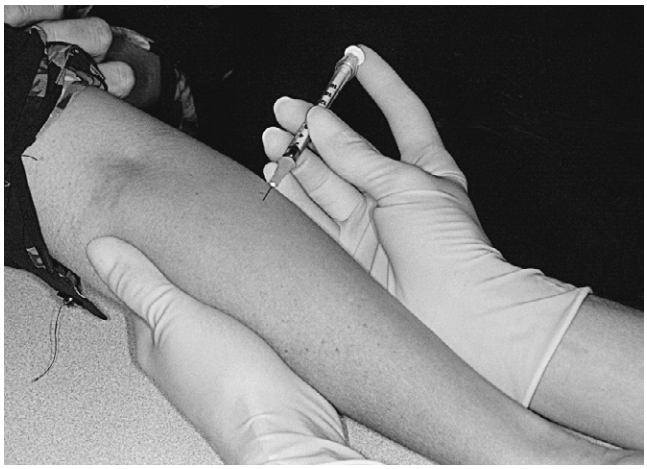

FIGURE 96-14 ■ A useful technique for performing a Mantoux tuberculin skin test on a child. The needle is applied perpendicular to the long axis of the arm to attain better control.

or patients can read positive skin test results accurately, but that they may not correctly interpret or report positive results has been well documented.[111,112,224,264,477] Two studies have demonstrated that pediatric care providers tend to underread Mantoux tuberculin skin tests.[77,285]

Several studies have shown great variability in readings of Mantoux tests.[37,83,312,477] Such variability can be minimized only by ongoing training of both testers and readers and by concentrating the responsibility of testing and reading to a small number of trained individuals.

The importance of the tuberculin test cannot be overemphasized as the main criterion for diagnosis of tuberculosis infection in an individual child. Only rarely is the tuberculin test response negative in an infected child, usually as a result of anergy from overwhelming infection, from viral infection, from HIV infection, from the use of immunosuppressive drugs, or because of factors not yet understood.[625] Anergy in tuberculosis can be selective for tuberculin; results of "control" skin tests may be positive but the Mantoux test result negative in a child with tuberculosis disease.[618] The utility of candidal or tetanus controls is limited and they are not recommended. In lieu of controls, clinicians need to be cognizant of the decreased sensitivity of the test in young children and immunocompromised patients.

The Mantoux test has a sensitivity and specificity of only approximately 95 percent at 10 mm of induration.[270] When a test with these characteristics is applied to a population with a 90 percent prevalence of tuberculosis infection, the positive predictive value of the skin test is 99 percent, an excellent result. However, if the same test is applied to a population with only a 1 percent prevalence of infection, the positive predictive value drops to 15 percent; 85 percent of the "positive" results are false-positive findings created by biologic variability, nonspecific reactions, and infection with environmental mycobacteria. These false-positive results lead to unnecessary treatment, cost, and anxiety for the patient, family, and clinician. In short, the low sensitivity and specificity of the tuberculin skin test render the test undesirable for use in persons from low-prevalence groups. The trend in the United States is to reduce or to eliminate routine testing of low-risk children but to target children with specific risk factors for one-time or periodic tuberculosis skin testing.[11,94,432]

In lieu of mass screening using tuberculin skin tests, children should be screened by history. Several recently published studies have shown that a questionnaire can be used in the United States to identify children with significant risk factors for tuberculosis infection, who then can receive a tuberculin skin test.[209,369,478,532] Factors that consistently correlate with having a positive tuberculin skin test result include contact with a case of tuberculosis, other family members with a positive tuberculin skin test result, and foreign birth or extensive travel to a high-prevalence country.[555] The predictive value of these questions may be diminished in high-prevalence areas.

The CDC and the American Academy of Pediatrics (AAP) have recommended varying the size of induration considered positive in various groups, according to their risk factors (Table 96-7). This is an attempt to increase sensitivity in children most likely to have rapid progression of asymptomatic tuberculosis infection to disease and to increase specificity in persons with no known risk factors for tuberculosis. In general in the United States, previous receipt of BCG vaccine should not influence interpretation of the initial tuberculin skin test of a child.[297]

TABLE 96-7 Amount of Induration in Reaction to a Mantoux Tuberculin Skin Test Considered Positive (Indicating Probable Infection with *Mycobacterium tuberculosis*)

Reaction Size	Risk Factors
≥5 mm	Contact with infectious cases
	Abnormal chest radiograph
	HIV infection or other immunocompromise
≥10 mm	Birth or previous residence in a high-prevalence country
	Residence in long-term care or corrections facility
	Certain medical risk factors: diabetes mellitus, silicosis, renal disease
	Occupation in health care field, exposure to patients with tuberculosis
	Member of a local high-risk group
	Close contact with a high-risk adult (except health care workers)
	Age <4 yr
≥15 mm	No risk factors

Interferon-γ Release Assays

Advances in molecular biology and genomics have led to use of alternatives to the tuberculin skin test.[480,609] Two new in vitro formats have been developed that measure interferon-γ release by sensitized lymphocytes after stimulation by *M. tuberculosis* antigens. Both formats use proteins—early secreted antigen target 6 and culture filtrate protein (CFP)-10—that are found on *M. tuberculosis* and only a few species of nontuberculous mycobacteria (*M. kansasii*, *M. marinum*, and *M. szulgai*) but not on the bacilli BCG or the *M. avium* complex. The first test licensed in the United States was QuantiFERON-TB and includes an extra antigen (TB7.7). The test measures whole-blood interferon production. The second format licensed in the United States is the enzyme-linked immunospot (T-SPOT.TB). This technique measures the number of mononuclear cells that produce interferon.

Both formats of interferon gamma release assays (IGRAs) have been studied primarily in adults.[480] Sensitivity in HIV-uninfected adults with disease has ranged from 73 to 96 percent,[421] and reported specificities range from 86 to 99 percent.[155,568] In HIV-infected adults with disease, sensitivity and specificity have ranged from 30 to 92 percent and 52 to 76 percent, respectively.[110,421] One meta-analysis of IGRA performance in HIV-uninfected adults with infection demonstrated specificities ranging from 98 to 100 percent.[154] There is some evidence that

the T-SPOT.TB is less affected by immunosuppression in HIV-infected adults than the QuantiFERON.[87]

In many clinical situations, these tests have a higher specificity than that of the tuberculin skin test, better correlation with surrogate measures of recent exposure to *M. tuberculosis* in low-incidence settings, and less cross-reactivity than does the tuberculin skin test because of previous BCG vaccination. Like the tuberculin skin test, interferon release assays cannot differentiate between tuberculosis infection and disease. Two clear advantages of the interferon release assays are the need for only one patient encounter (vs. two with the tuberculin skin test) and the lack of possible boosting of the result, because the patient is not exposed to any biologic material. It is unclear to what degree an IGRA can be boosted by a preceding tuberculin skin test. One meta-analysis reported substantial within-subject variation in IGRAs before and after tuberculin skin testing, but the frequency varied dramatically (16% to 80%).[675] Two more recent studies did not demonstrated boosting.[525,543] Although the potential risk for boosting can be avoided by obtaining the IGRA before or at the same time as placing the tuberculin skin test, prior receipt of a tuberculin skin test is not a contraindication to IGRA use.

There are fewer pediatric studies of IGRAs. Sensitivity in children with microbiologically confirmed or all children diagnosed with tuberculosis disease (clinically diagnosed disease and microbiologically confirmed) has ranged from 53 to 100 percent and from 53 to 94 percent, respectively.[380] There is no reference standard for the diagnosis of latent tuberculosis infection. Concordance between the tuberculin skin test and IGRAs varies widely. Although high concordance (> 90%) has been reported from low-prevalence settings where BCG is not used, concordance decreases in BCG-immunized children.[46,130,380] When tuberculin skin testing and IGRAs offer discordant results, the clinician must make the determination of which test to rely on. One reasonable approach is to use the more specific IGRA in an older (≥ 5 years old) immunocompetent child lacking specific TB risk factors, aside from birth in a high-prevalence nation. For younger children, children identified via contact investigations or with contact with persons suspected of having tuberculosis disease, immunocompromised children of any age, or children in whom tuberculosis disease is suspected, then any test being positive would be considered positive.

The performance of IGRAs is limited in certain groups. Immunocompromised children, including those with cancer[620] and HIV infection,[128,303,387] are more likely to have indeterminate test results,[243] as are children younger than 2 years of age.[303] Whereas some studies have shown no association between indeterminate results (usually due to failure of the positive control) and age,[490] others have reported high rates of indeterminate test results in children younger than 4 or 5 years of age.[46,130] Helminthic infections have also been associated with indeterminate results,[655] a particular concern when screening international adoptees.

Reversions and conversions of IGRAs have been described in HIV-infected children being treated for tuberculosis disease.[128] Determining performance for children with tuberculosis infection is more challenging, because there is no reference standard. One proxy is degree of exposure to a documented source case. Sensitivity and specificity for infection have ranged from 90 to 92 percent and 91 to 95 percent, respectively.[380] IGRAs appear to correlate more closely than tuberculin skin tests for BCG-vaccinated children identified in contact investigations.[199] However, data are conflicting and other studies have shown similar performance for the tuberculin skin test and IGRAs for the diagnosis of pediatric tuberculosis infection.[4] The sensitivity of IGRAs and the tuberculin skin test declines with decreasing age and in HIV-infected children.[387]

The CDC has suggested that IGRAs be used with caution in children younger than 5 years of age given the relative paucity of data for this age group.[102] One optimal use for these assays may be in the BCG-immunized older child (≥5 years of age) who lacks tuberculosis risk factors aside from birth in a high-prevalence nation. Another use may be for a child whose family is reluctant to treat infection based on a tuberculin skin test result alone. In children in whom one suspects disease, obtaining IGRAs may provide indirect evidence for tuberculosis in instances where the child is anergic to the tuberculin skin test. Because most studies have not shown a consistent, significant difference between the 2 IGRAs, the CDC recommends that the assays may be used interchangeably.[102]

Given the brief period of time during which IGRAs have been used, many questions remain unanswered. Some relate to the dynamics of IGRAs—when they become positive after exposure to a person with tuberculosis disease, how long they remain positive, and the degree to which conversions and reversions occur on therapy. These questions may be best answered with longitudinal studies.

Diagnostic Mycobacteriology in Children

The demonstration of acid-fast bacilli in stained smears of sputum is presumptive evidence of pulmonary tuberculosis in most patients.[536] However, in children, tubercle bacilli usually are relatively few. Gastric washings, which often are used in lieu of sputum, can be contaminated with acid-fast organisms from the mouth. Tubercle bacilli in CSF, pleural fluid, lymph node aspirate, and urine are sparse; thus, only rarely are direct-stained smears for tubercle bacilli of any use in pediatric practice.[628] Cultures for tubercle bacilli are of great importance, not only to confirm the diagnosis but increasingly to permit testing for drug susceptibility. If culture and drug susceptibility data are available from the associated adult case and the child has classic features of tuberculosis (positive skin test result, consistent abnormal chest radiograph), obtaining cultures from the child adds little to management.

Painstaking collection of specimens is essential for diagnosis of children because fewer organisms usually are present than in adults.[579] Gastric lavage should be performed in the very early morning, when the patient has had nothing to eat or drink for 8 hours and before the patient has a chance to wake up and start swallowing

saliva, which could dilute the bronchial secretions that were brought up during the night and made their way into the stomach. The stomach contents should be aspirated first. No more than 50 to 75 mL of sterile distilled water (not saline) should be injected through the stomach tube and the aspirate added to the first collection. The gastric acidity (poorly tolerated by tubercle bacilli) should be neutralized immediately. Concentration and culture should be performed as soon as possible after collection. However, even with optimal, in-hospital collection of three early-morning gastric aspirate samples, *M. tuberculosis* can be isolated from only 30 to 40 percent of children and 70 percent of infants with pulmonary tuberculosis.[76,618,670]

Sputum induction is an alternative to gastric aspiration. Sputum induction is an outpatient procedure that can be performed in clinic settings[436] and requires the child to be fasting for only 3 hours. A nebulized treatment with a β agonist is given, followed by a nebulized treatment with hypertonic saline. The β agonist decreases the risk for bronchospasm occasionally seen with hypertonic saline. Saline increases the tussive force in children (even those who had no cough initially). As children begin to cough up secretions, the child's oropharynx is suctioned. One study from a high-prevalence nation showed that one specimen obtained via sputum induction had the same smear and culture yield as three gastric aspirates.[282,722] Sputum induction in HIV-infected and HIV-uninfected adults had the same diagnostic yield as specimens obtained via bronchoscopy.[127] In most studies, the yield of *M. tuberculosis* from bronchoscopy specimens has been lower than from properly obtained gastric aspirates.[1,104]

CSF, pleural fluid, and synovial fluid (as much fluid as possible should be collected) usually are centrifuged, and the sediment is used for stained smear and culture. An overnight urine specimen should be obtained in the early morning and taken immediately to the laboratory for processing because the organisms tolerate the low pH of urine poorly. Lymph node aspirates and biopsy tissue can be inoculated directly into a fluid medium such as Middlebrook 7H9.

Staining and examination of smears as well as inoculation of special media, incubation in a carbon dioxide environment, strain differentiation based on many cultural characteristics, and drug susceptibility testing require equipment, skills, and experience beyond those available in the usual clinic or hospital laboratory.[250] Thus, most laboratories depend on regional or reference laboratories for procedures beyond their scope.

Traditional drug susceptibility testing ordinarily is performed for isoniazid, rifampin, ethambutol, and streptomycin. Pyrazinamide susceptibilities are not routinely performed owing to testing complexities. Drug susceptibilities are performed using one of two systems: agar proportions and growth in liquid media. For agar proportions, the organism is inoculated onto two plates: one with a specified concentration of an antibiotic and one that is drug free. The proportion of colonies on each plate is compared, and if there is more growth on the antibiotic plate, the isolate is considered resistant to that drug. For automated liquid media systems (e.g., BACTEC), the isolate is inoculated into vials with and without antibiotic. If the drug-containing vial grows faster than or at the same rate as the drug-free vial, then the isolate is considered resistant to that drug. Susceptibilities to other medications can be requested if the isolate is resistant to first-line medications.

Pyrosequencing, detecting pyrophosphate release during DNA synthesis, has been used to detect mutations associated with resistance to several first- and second-line medications. One advantage is the ability of pyrosequencing to detect mutations in multiple loci in several isolates in real time.[197]

Nucleic Acid Amplification

The main form of nucleic acid amplification studied in children with tuberculosis is PCR, which uses specific DNA sequences as markers for microorganisms.[188,389,433] Various PCR techniques, most using the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms,[11,88] have a sensitivity and specificity of more than 90 percent in comparison to sputum culture for detecting pulmonary tuberculosis in adults. Other advantages include the ability to detect even low organism burdens, a particular consideration in children with paucibacillary disease; rapidity of results and decreased time to initiation of therapy and patients lost to follow-up; ability to differentiate between *M. tuberculosis* and nontuberculous mycobacterial species; and potentially diminished biosafety requirements.[458] Disadvantages include diminished sensitivity in patients with smear-negative disease; expense of equipment; variation in test performance even among reference laboratories[463,705]; and concern for cross-contamination.

Evaluation of PCR in childhood tuberculosis has been limited. Compared with a clinical diagnosis of pulmonary tuberculosis in children, the sensitivity of PCR has varied from 25 to 83 percent and specificity has varied from 80 to 100 percent.[433,466,488,553,590] PCR of stool had a sensitivity of 30 to 40 percent and a specificity of 100 percent in children with pulmonary tuberculosis,[709] offering a noninvasive diagnostic modality. PCR of gastric aspirates may be positive in a recently infected child even when the chest radiograph is normal, demonstrating the occasional arbitrariness of the distinction between tuberculosis infection and disease in children. PCR may have a useful but limited role in evaluating children for tuberculosis. A negative PCR analysis never eliminates tuberculosis as a diagnostic possibility, and a positive result does not confirm it. PCR may be particularly helpful in evaluating immunocompromised children with pulmonary disease, especially those with HIV infection, although published reports of its performance in such children are lacking. PCR also may aid in confirming the diagnosis of extrapulmonary tuberculosis, but only a few reports have been published.[218,386,425]

Xpert TB/RIF is a real-time PCR assay for *M. tuberculosis* that simultaneously detects rifampin resistance. Rifampin resistance is used as a proxy for MDR-TB, because rifampin monoresistance is uncommon.[171] Rifampin mutations, in contrast to isoniazid mutations, cluster on a small part of the mycobacterial genome and

synonymous mutations are rare, facilitating molecular detection of drug resistance. This assay uses a self-contained cartridge system and is not as operator dependent as traditional PCR. Sensitivity and specificity were 72 to 77 percent and 99 percent in smear-negative adults and 98 to 99 percent and 99 to 100 percent in smear-positive adults, respectively and performed equivalently in HIV-infected and HIV-uninfected adults.[62] The two pediatric studies to date comparing Xpert TB/RIF to culture showed a sensitivity of 100 percent in smear-positive children and 61 to 67 percent in smear-negative children, with a specificity of 99 to 100 percent.[459,508] Smear microscopy, in contrast, had a sensitivity of 39 percent and a specificity of 100 percent.[459] Although cartridges for the Xpert system are expensive, the self-contained system offers advantages in rapid detection of MDR-TB and the prospect of increasing available diagnostics in settings that lack laboratory infrastructure. However, Xpert should not replace the need for obtaining mycobacterial cultures. The need to identify additional drugs to which the isolate is susceptible is crucial for advancing patient care.

TREATMENT

Management of Tuberculous Children

Treatment of cavitary tuberculosis in adults is one of the most scientifically accurate areas in all of medicine and one of the finest examples of international professional cooperation in all of history. The ability to quantify the extent of disease and the large numbers of cases of tuberculosis have allowed researchers to address specific questions about optimal drug regimens and doses, duration of therapy, and nonmedical management. Historically, treatment recommendations for children have been extrapolated from data in adults. However, during the past 3 decades, a large number of treatment trials for children have been reported, which has led to dramatic changes in the therapeutic approach to childhood tuberculosis.

As recently as the early 1980s, the recommended treatment duration for children with tuberculosis disease was 12 to 18 months. Although these regimens are effective when they are used properly, actual failure rates are high because of poor adherence during the long period of treatment. Newer regimens often are called short-course chemotherapy because treatment durations as short as 6 months are routinely successful. However, the key to the new approach is not the short duration but the intensive initial therapy with three or more antituberculosis drugs.

Antituberculosis Drugs (Tables 96-8 and 96-9)

Isoniazid is the mainstay of therapy for tuberculosis in children. Inexpensive, bactericidal, of low molecular weight and therefore readily diffusible to all tissues in the body, [163] and relatively nontoxic to children, isoniazid is one of the most nearly perfect drugs in the pediatrician's armamentarium. It can be administered orally, intramuscularly, or intravenously. When the drug is taken orally, high plasma, sputum, and CSF levels are reached within a few hours and persist for at least 6 to 8 hours.[342,471] Because of the slow multiplication of *M. tuberculosis*, the total daily dose can be given at one time. The usual level necessary to inhibit multiplication of tubercle bacilli is 0.02 to 0.05 μg/mL.

Human variation in the acetylation rate of isoniazid to an inactive compound is known to be determined genetically.[405] Rapid acetylation occurs more frequently in blacks and Asians than in whites. Although a simple method, specifically the use of a urine sample, now is available for classifying patients as slow or rapid inactivators of isoniazid, the normal way of coping with the problem in children has been to give a sufficiently large dose of isoniazid to ensure an adequate level even in rapid inactivators.[403,681]

The principal toxic effects of isoniazid are peripheral neuritis and hepatitis. Peripheral neuritis resulting from competitive inhibition of pyridoxine utilization is a rare event in North American children because both milk and meat are the main dietary sources of pyridoxine.[54] In some well-nourished children, serum pyridoxine concentrations are depressed by isoniazid but clinical signs are not apparent.[495] In the case of most children, therefore, the use of supplementary pyridoxine is not necessary. However, in teenagers whose diets may be inadequate, in children from ethnic groups with low milk and meat intake, in HIV-infected children, and in breast-fed infants, pyridoxine supplementation (25 to 50 mg/day) is important. Peripheral neuritis, when it does occur, usually is manifested by "pins and needles" sensations in the hands and feet.

The risk for development of hepatotoxicity from isoniazid, which is rare in children, increases in frequency with age.* Its cause is unclear.[332] Rapid acetylators are no more susceptible than are slow acetylators.[190,403] Simultaneous use of alcohol, phenytoin, piperazine, and especially rifampin seems to increase the likelihood of hepatotoxicity.[86,336] Monitoring of aspartate aminotransferase and alanine aminotransferase activity sometimes reveals transient increases during treatment with isoniazid, but the levels usually return spontaneously to normal without interruption of treatment.[483] Liver enzyme abnormalities in adolescents receiving isoniazid are common occurrences and usually disappear spontaneously, but severe hepatitis can occur.[370,595] The estimated incidence of hepatic failure in children on isoniazid monotherapy was 3.2/100,000,[717] jaundice was rare (0.06%), and transient elevations in hepatic transaminase levels were seen in 8 percent.[162] In children receiving isoniazid as part of multidrug therapy, rates of jaundice and elevated hepatic transaminase levels are higher, but still extremely low.[162]

The possible occurrence of hepatitis raises the question of routine monitoring of liver enzyme levels once a month in all children receiving isoniazid. The advantage of doing so has to be weighed not only against the expense but particularly against the difficulty of ensuring regular

TABLE 96-8 Commonly Used Drugs for the Treatment of Tuberculosis in Children

Drug	Dosage Forms	Daily Dose (mg/kg/day)	Twice-Weekly Dose (mg/kg/dose)	Thrice-Weekly Dose (mg/kg/dose)	Maximal Daily Dose
Ethambutol	Tablets 100 mg 400 mg	20-25	50	Not recommended for young children 1.5 g if 40-55 kg 2.5 g if 56-75 kg 3 g if >75 kg	2.5 g
Isoniazid*†	Scored tablets: 100 mg 300 mg Syrup:‡ 10 mg/mL	10-15†	20-30	15	Daily: 300 mg Twice weekly: 900 mg Thrice weekly: 900 mg
Pyrazinamide	Scored tablets: 500 mg	20-40	50 (max: 2 g) if <56 kg 3 g if 56-75 kg 4 g if >75 kg	Not recommended for young children 1.5 g if 40-55 kg 3 g if 56-75 kg 4 g if >75 kg	2 g
Rifampin*	Capsules: 150 mg 300 mg Syrup: Formulated in syrup from capsules	10-20	10-20	Not recommended for young children Adolescents: 10	Daily: 600 mg Twice weekly: 900 mg
Streptomycin	Vials: 1 g 4 g	20-40	20-40		1 g

*Rifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (>50 kg body weight) daily doses of each drug.
†When isoniazid is used in combination with rifampin, the incidence of hepatotoxicity increases if the isoniazid dose exceeds 10 mg/kg/day.
‡Most experts advise against the use of isoniazid syrup because of instability and a high rate of gastrointestinal adverse reaction (diarrhea, cramps).

TABLE 96-9 Drugs for Treatment of Drug-Resistant Tuberculosis in Children*

Drugs	Dosage Forms	Daily Dosage (mg/kg/day)	Maximum Daily Dose
Amikacin	Vials: 500 mg, 1 g	15-30 (IM, IV)	1 g
Capreomycin	Vials: 1 g	15-30 (IM, IV)	1 g
Clofazimine	Capsules: 50 mg 100 mg	50-100 mg/day	200 mg
Cycloserine	Capsules: 250 mg	10-20	1 g
Ethionamide	Tablets: 250 mg	15-20 given in two or three divided doses	1 g
Kanamycin	Vials: 75 mg/2 mL 500 mg/2 mL 1 g/3 mL	15-30 (IM, IV)	1 g
Levofloxacin	Tablets: 250 mg 500 mg 750 mg	Adults: 500-750 mg total/day Pediatric: 7.5-10 mg	1000 mg
Linezolid	Vials: 2 mg/mL Tablets: 600 mg Suspension: 20 mg/mL	10 (PO, IV)	600 mg
p-Aminosalicylic acid	Packets: 4 g	200-300 given in two to four divided doses	12 g

IM, intramuscularly; *IV,* intravenously; *PO,* orally.
*There are no data to support intermittent dosing for second-line medications except for injectable agents.

monthly visits if the patient and parents know that every clinic visit entails a venipuncture. Most experts prefer to substitute routine questions about appetite and well-being, determination of weight, and a check of the appearance of the sclera and the size of the liver.[77,493] Patients should be counseled to stop taking isoniazid and to contact the clinician immediately if significant nausea, vomiting, abdominal pain, or jaundice occurs during the use of isoniazid.

Allergic manifestations of isoniazid hypersensitivity are extraordinarily rare. Convulsions have been reported after doses of 100 mg/kg or more, as in suicide attempts.[410,461,485,570] The treatment for isoniazid overdose is intravenous pyridoxine.

The usual dosage in children is 10 to 15 mg/kg/day, to a maximum of 300 mg/day. Isoniazid is available in tablets of 100 and 300 mg. A syrup of isoniazid in sorbitol (10 mg/mL) also is available; however, it is unstable at 37° C and should be kept cool. Significant gastrointestinal intolerance (nausea, diarrhea) develops in many children while they are taking the isoniazid suspension. If tablets are used, they are crushed easily in a dessert spoon, to which then is added in the same spoon a vehicle such as applesauce, mashed banana, or another palatable medium. The crushed tablets must never be added to the nursing bottle or offered in milk or water because they will be ingested only partially. If isoniazid is given concurrently with rifampin, the dose should not exceed 10 mg/kg/day.[468] If the intramuscular form is used, for example, in a child with meningitis who is vomiting, the daily dose is the same as the daily oral dose but usually is divided and given every 8 to 12 hours. Isoniazid can interact with several other drugs, particularly theophylline, and the dosage of each may need to be modified in a patient taking several drugs.[28] Isoniazid also can increase serum phenytoin levels by blocking its metabolism in the liver, thereby leading to toxicity.[424]

RIF is a semisynthetic drug derived from *Streptomyces mediterranei*. Active against a wide variety of both intracellular and extracellular organisms, it is bactericidal and more effective against mycobacteria than is any other drug except isoniazid. Most clinical isolates are susceptible to 5 μg/mL or less. The drug is absorbed readily from the gastrointestinal tract in the fasting state; peak serum levels of 6 to 10 μg/mL are achieved within 2 hours, and the drug is distributed widely in body fluids and tissues, including CSF. Excretion is mainly through the biliary tract; however, effective levels are achieved in the kidneys and urine. In many patients receiving treatment with rifampin, tears, saliva, urine, and stool turn orange as the result of a harmless metabolite, but patients and parents always must be warned in advance. Drawbacks include the relatively high cost; the rare occurrence of explosive hypersensitivity reactions with hemolytic anemia (associated with intermittent rifampin therapy[214]); and the occasional occurrence of leukopenia or thrombocytopenia (associated with daily rifampin[225]). Rifampin has a number of drug interactions, including inactivation of oral contraceptives. It decreases levels of protease inhibitors, thus limiting its use in HIV-coinfected children on antiretroviral therapy. Rifabutin is preferred in this circumstance. Finally, there is a "therapeutic orphan" clause in the United States for children younger than 5 years, which also means that no formulation is commercially available for young children. However, rifampin easily can be made into a suspension for use in children.

Rifampin should be used alone only in treating tuberculosis infection with an isoniazid-resistant organism or for children who do not tolerate isoniazid. If isoniazid 20 mg/kg and RIF 15 to 20 mg/kg are used, the incidence of hepatotoxicity is appreciable. Therefore, when the two are used together, one would be wise to approximate the doses to isoniazid 10 mg/kg and RIF 15 to 20 mg/kg. Rifamate is a capsule containing both isoniazid (150 mg) and rifampin (300 mg). Two capsules supply the usual adult (more than 50 kg) daily dose of each drug. Rifamate may be appropriate for older children and adolescents.[3] Rifater contains isoniazid, rifampin, and pyrazinamide together in one pill in varying concentrations. Rifapentine is a new rifamycin with a very long half-life, allowing for weekly administration. It is now recommended in combination therapy with isoniazid for the treatment of tuberculosis infection for persons 12 years of age or above.[626] This regimen currently is recommended only under directly observed preventive therapy. Few pharmacokinetic data for rifapentine are available for young children. It appears that children require larger weight-normalized doses than adults.[56] Long-term efficacy data for children and adolescents are scant.

Pyrazinamide contributes to the killing of *M. tuberculosis*, particularly at a low pH, such as within macrophages.[535] The exact mechanism of action of this agent is a subject of controversy. Pyrazinamide has no effect on extracellular tubercle bacilli in vitro but clearly contributes to the killing of intracellular bacilli. Primary resistance is very rare, except that *Mycobacterium bovis* is intrinsically resistant. The drug diffuses readily into all areas, including CSF.[161,191] The usual adult daily dose is 30 to 40 mg/kg. The adult dose is tolerated well by children, results in high CSF concentrations, and clearly is effective in therapy trials for tuberculosis in children.[167,528,539,611] However, serum concentrations are lower in children than in adults taking a weight-equivalent dose.[222] Pyrazinamide appears to exert its maximal effect during the first 2 months of therapy. Hepatotoxicity can occur at high doses but rarely does at the usual dose. Pyrazinamide routinely causes an increase in serum uric acid concentration by inhibiting its excretion through the kidneys. Toxic reactions in adults include flushing, cutaneous hypersensitivity, arthralgia, and overt gout; however, the considerable experience with this drug in children in Latin American countries, Hong Kong, and the United States has revealed few problems. It plays a major role in intensive, short-course treatment regimens.[215,611] Use of pyrazinamide for the first 2 months allows therapy to be shortened from 9 to 6 months for most nonskeletal, nonmeningeal forms of tuberculosis.

Ethambutol has been used for many years as a companion drug for isoniazid in adults. The usual oral dose is 20 mg/kg/day.[164] At this dose, the drug primarily is bacteriostatic, its major role being to prevent the emergence of resistance to other drugs. However, at doses of 25 mg/kg/day or 50 mg/kg given twice a week,

ethambutol has some bactericidal action.[129,210] Unfortunately, at these higher doses, optic neuritis or red-green color blindness has occurred in some adults. Regular visual field and color chart testing should detect these reversible effects early. The incidence of ophthalmologic toxicity in children is extremely low (0.05%), if it occurs at all, in part because children metabolize the drug faster than adults.[164] It is used frequently and safely in children, including in preverbal children in whom visual acuity evaluation is not possible, with life-threatening forms of tuberculosis or who are at risk for drug-resistant tuberculosis. However, it diffuses poorly into CSF.[161] In the United States, it is used with isoniazid, rifampin, and pyrazinamide as first-line therapy for children with suspected tuberculosis when drug-susceptibility results are not yet known.

Ethionamide is an effective and well-tolerated drug in children at a dose of 15 to 20 mg/kg/day divided into two or three doses given after meals. Children rarely complain about its sulfurous taste, which is repulsive to adults. Related to isoniazid, it likewise diffuses readily into CSF.[166,168,271] Ethionamide is used in cases of drug-resistant tuberculosis and tuberculous meningitis, where it can replace ethambutol in the regimen. Unfortunately, no convenient pediatric dosage form is available. Use of ethionamide may be limited by its most common side effect—vomiting. Ethionamide resistance is common in children with isoniazid resistance.[550]

Second-line medications are used when patients have drug-resistant strains of *M. tuberculosis* or when they are intolerant of first-line mediations. Second-line medications are notable for more frequent or severe adverse effects, fewer pediatric pharmacokinetic data, and fewer available child-friendly formulations than first-line drugs. Drug susceptibility testing for some second-line agents (cycloserine, linezolid, clofazimine) is less well-validated than for first-line medications, and correlation between in vitro susceptibility and clinical response is less evident.

Streptomycin is used in conjunction with isoniazid and rifampin in life-threatening forms of tuberculosis. It is bactericidal and tolerated well in children in the usual dose of 20 to 40 mg/kg/day intramuscularly up to 1 g. Usually, streptomycin can be discontinued within 1 to 3 months if clinical improvement is definite, whereas the other two or three drugs are continued by mouth. Use of streptomycin and other injectable drugs (amikacin, capreomycin, kanamycin) is limited by the dose-dependent incidence of ototoxicity and nephrotoxicity. An isolate may be resistant to some injectable agents and remain susceptible to others.

p-Aminosalicylic acid formerly was part of the standard treatment of tuberculosis. However, it is a purely bacteriostatic drug that has been superseded by more powerful drugs (e.g., rifampin, pyrazinamide). It is used only for the treatment of drug-resistant tuberculosis. Cycloserine, linezolid, and clofazimine are other drugs sometimes used in patients with MDR-TB.[561] Cycloserine diffuses well into tissues and CSF,[161] but its use may be limited by neuropsychiatric side effects,[656] which are more common in adults. Linezolid demonstrates modest early bactericidal activity but little extended early bactericidal activity[156]; its use may be limited by optic neuritis, peripheral neuropathy, and bone marrow suppression. Clofazimine has anti-inflammatory properties, and there is little documented resistance; its use may be limited by skin pigment changes.[116]

Several of the fluoroquinolones, especially levofloxacin and moxifloxacin, have significant antituberculosis activity,[315,430] but they cannot be used routinely in children with drug-susceptible tuberculosis because of the possible destruction of growing cartilage seen in animal models. However, the dire consequences of drug-resistant tuberculosis lead many experts to use them successfully and with little apparent toxicity in children with MDR-TB disease.[562] These drugs are bactericidal and diffuse into tissues and CSF well.[161] If an isolate is resistant to one fluoroquinolone, resistance to other fluoroquinolones is common.

Microbiologic Basis for Treatment

Laboratory observations of *M. tuberculosis* and the results of clinical therapy trials have led to a hypothesis concerning the actions of various drugs and drug combinations.[181,225,427,428] The tubercle bacillus can be killed only during replication, which occurs in organisms that are active metabolically. In one model, bacilli in a host exist in different populations (Table 96-10). They are active metabolically and replicate freely where oxygen tension is high and the pH is neutral or alkaline. Environmental conditions for growth are best within cavities, and such conditions can lead to a large bacterial population. Adults with reactivation-type pulmonary tuberculosis usually have all three populations of tubercle bacilli. Children with pulmonary tuberculosis and patients of all ages with only extrapulmonary tuberculosis are infected with a much smaller number of tubercle bacilli because the cavitary population is not present.

Naturally occurring drug-resistant mutant organisms occur within large populations of tubercle bacilli even before chemotherapy is started. All known genetic loci for drug resistance in *M. tuberculosis* are located on the chromosome; no plasmid-mediated resistance is known. The rate of resistance within populations of organisms is

TABLE 96-10 **In Vivo Location of *Mycobacterium tuberculosis*: A Model**

Location	Population Size	Metabolism and Replication	pH	Most Effective Drugs
Cavity	10^7-10^9	Active and rapid	Neutral or alkaline	INH, RIF, STM
Closed caseous lesions	10^5-10^7	Slow and intermittent	Neutral	RIF, INH
Within macrophages	10^4-10^6	Very slow	Acid	PZA, RIF, INH

INH, isoniazid; *PZA,* pyrazinamide; *RIF,* rifampin; *STM,* streptomycin.

related to the rate of mutations at these loci.[416,641,647,724,725] Although a large population of bacilli as a whole may be considered drug susceptible, a subpopulation of drug-resistant organisms occurs at a fairly predictable rate. The mean frequency of these drug-resistant mutants is about 10^{-6} but varies among drugs: streptomycin, 10^{-5}; isoniazid, 10^{-6}; and rifampin, 10^{-7}.[143] A cavity containing 10^{9} tubercle bacilli has thousands of single drug–resistant mutant organisms, whereas a closed caseous lesion contains few if any resistant mutants.

The two microbiologic properties of population size and drug resistance mutation explain why single antituberculosis drugs cannot cure cavitary tuberculosis. In the mid 1940s, streptomycin alone was given to adults with cavitary pulmonary tuberculosis.[411] Within 3 months, 80 percent of patients had significant numbers of streptomycin-resistant organisms. This phenomenon has been observed for every antituberculosis drug developed subsequently. However, the natural occurrence of resistance to one drug is independent of resistance to any other drug because the resistance loci are not linked. The chance of having even one organism "naturally" resistant to two drugs is on the order of 10^{-11} to 10^{-13}. Populations of this size in patients are extremely rare, and mutants naturally resistant to two drugs are nonexistent.

The population size of tubercle bacilli within a patient determines the appropriate therapy. For patients with large bacterial populations (adults with cavities or extensive infiltrates), many single drug–resistant mutants are present and at least two antituberculosis drugs must be used.[145] Conversely, for patients with tuberculosis infection but no disease, the bacterial population is small (10^{3} to 10^{4} organisms), drug-resistant mutants are rare findings, and a single drug can be used. Children with pulmonary tuberculosis and patients of all ages with extrapulmonary tuberculosis have medium-sized populations in which drug-resistant mutants may or may not be present. In general, these patients should be treated with at least two drugs.

Some antituberculosis drugs, such as isoniazid, rifampin, streptomycin, and fluoroquinolones are bactericidal against *M. tuberculosis*. Other drugs, including ethionamide, *p*-aminosalicylic acid, and low-dose ethambutol, are bacteriostatic. The earliest treatment regimens for tuberculosis combined the killing action of a bactericidal drug with a bacteriostatic drug that would suppress replication of drug-resistant mutant organisms. A small number of organisms survived despite administration of chemotherapy, and 18 to 24 months of treatment was necessary to permit host defenses to eliminate persisting organisms. Despite the prolonged treatment period, relapse rates were 5 to 15 percent, mostly a result of poor adherence to treatment.

The availability of rifampin and the rediscovery of pyrazinamide in the early 1970s effected radical change in antituberculosis chemotherapy. These two drugs have the most potent sterilizing action, the ability to kill tubercle bacilli within lesions as quickly as possible. The addition of rifampin to isoniazid for the treatment of pulmonary tuberculosis leads to cure rates approaching 100 percent with only 9 months of treatment. The further addition of pyrazinamide shortens the necessary treatment duration to only 6 months.

Treatment of the Stages of Tuberculosis

Exposure

Children exposed to potentially infectious adults with pulmonary tuberculosis should begin treatment, usually with isoniazid only, if the child is younger than age 5 years or has other risk factors for the rapid development of tuberculosis disease, such as immunocompromise.[631,711] Failure to do so may result in the development of severe tuberculosis disease even before the tuberculin skin test becomes reactive; the "incubation period" of disease may be shorter than that for the skin test. The child is treated for a minimum of 2 months after contact with the infectious case is broken (by physical separation or by effective treatment of the case). After 2 months, the tuberculin skin test is repeated. If the second test result is positive, infection is documented and isoniazid should be continued for a total duration of 9 months; if the second skin test result is negative, treatment can be discontinued. If the exposure was to a person with an isoniazid-resistant but rifampin-susceptible isolate, then rifampin is the recommended treatment.

Two special circumstances of exposure deserve attention. A difficult situation arises when exposed children are anergic because of HIV infection. These children are particularly vulnerable to rapid progression of tuberculosis, and it will not be possible to determine whether infection has occurred. In general, these children should be treated as though they have tuberculosis infection.

The second situation is potential exposure of a neonate to a mother (or other adult) with a positive tuberculin skin test result or, rarely, a nursery worker with contagious tuberculosis.[357,624] Management is based on further evaluation of the mother:

1. *The mother has a normal chest radiograph:* no separation of the infant and mother is required. Although the mother should receive treatment for tuberculosis infection and other household members should be evaluated for tuberculosis infection or disease, the infant needs no further workup and no treatment is needed unless a case of disease is found.
2. *The mother has an abnormal chest radiograph:* the mother and child should be separated until the mother has been evaluated thoroughly. If the radiograph, history, physical examination, and analysis of sputum reveal no evidence of pulmonary tuberculosis in the mother, a reasonable assumption is that the infant is at low risk for acquiring infection. The radiographic abnormality is due to another cause or a quiescent focus of previous tuberculosis infection. However, if the mother remains untreated, contagious tuberculosis may develop later and the infant will be exposed. Both the mother and infant should receive appropriate follow-up care, but the infant does not need treatment. If the radiograph and clinical history are suggestive of pulmonary tuberculosis, the child and mother should remain

separated until both have begun appropriate chemotherapy. The infant should be evaluated for congenital tuberculosis. The placenta should be examined. If the mother has no risk factors for drug-resistant tuberculosis, the infant should receive isoniazid and close follow-up care. The infant should have a tuberculin skin test at 3 or 4 months after the mother is judged to be contagious no longer; evaluation of the infant at this time follows the guidelines for other exposure of children. If no infection is documented at this time, repeating the tuberculin skin test in 6 to 12 months would be prudent. If the mother has tuberculosis caused by a multidrug-resistant isolate of *M. tuberculosis* or she has poor adherence to therapy, the child should remain separated from her until she is no longer contagious or the infant can be given BCG vaccine and be kept separated until the vaccine "takes" (marked by a reactive tuberculin skin test).

Infection

The recommendation for treatment of asymptomatic tuberculin-positive individuals is based on data from several well-controlled studies; it applies particularly to children and adolescents who are at high risk for the development of overt disease but at very low risk for development of the main toxic manifestation of isoniazid therapy, which is hepatitis.[170,202,455,468,597] The large, carefully controlled U.S. Public Health Study of 1955, followed by others both in this country and abroad, demonstrated the favorable effect of 12 months of isoniazid on the incidence of complications as a result of both lymphohematogenous and pulmonary spread.[268] The younger the tuberculin reactor, the greater the benefit.[126]

The American Thoracic Society and the CDC[13] recommend that isoniazid for treatment of tuberculosis infection be given to the following groups:

- Household members and other close associates of potentially infectious tuberculosis cases. All contacts of any age with a Mantoux tuberculin skin test reading of 5 mm or greater and without a documented history of reaction in the past or with a positive interferon gamma release assay (IGRA) should be considered recently infected and receive therapy if they have not been previously treated.
- Newly infected people, regardless of age, who have had a tuberculin skin test or IGRA conversion within the past 2 years.
- People with HIV infection who have a reaction of 5 mm or greater to a Mantoux test.
- People of any age with tuberculosis infection in the past who received inadequate treatment.
- People of any age with a positive tuberculin skin test or positive IGRA and an abnormal but stable chest radiograph.
- People with significant tuberculin reactions or positive IGRAs who have special clinical situations, including silicosis, diabetes mellitus, prolonged corticosteroid therapy, immunosuppressive therapy, hematologic malignant disease, and end-stage renal disease.
- All children and adolescents with a "positive" tuberculin skin test reaction or interferon release assay result.

The question arises regarding how long the protective effect can be expected to last. Comstock and associates,[124] in their final report on isoniazid prophylaxis in Alaska, demonstrated the protective effect of 1 year of chemoprophylaxis to be at least 19 years. Hsu[267] described 2494 patients monitored for up to 30 years and showed that adequate drug prophylaxis prevented reactivation of tuberculosis infection during adolescence and into young adulthood. It seems reasonable to hope that the decreased risk for active tuberculosis after isoniazid prophylaxis may, in fact, be lifelong in individuals infected with isoniazid-susceptible tubercle bacilli. Failure of isoniazid after exposure to isoniazid-resistant *M. tuberculosis* has been documented. No controlled study of an alternative regimen has been reported. Rifampin alone is recommended and widely used, although failures have been reported.[368]

The duration of isoniazid treatment initially was set arbitrarily at 12 months.[281] A large trial comparing regimens of daily isoniazid for 12, 24, and 52 weeks with placebo for their ability to prevent tuberculosis disease was conducted in eastern Europe with adults who had old fibrotic lesions caused by tuberculosis. Therapy for 1 year was most effective, especially if the patients were adherent to it. However, therapy for 24 weeks afforded a fairly high level of protection. A subsequent analysis concluded that the 24-week duration of preventive therapy was more cost effective for adults than was the 52-week duration.[596] Subsequently, many health departments have accepted 6 months of isoniazid preventive therapy as their standard regimen for adults. However, the cost-effectiveness analysis does not apply to children. A recent review of all published studies concluded that the effectiveness of isoniazid therapy increased up to 9 months' duration, but no additional benefit was achieved with a longer duration.[13] AAP and CDC recommended regimens[13] for tuberculosis infection include the following:

- 9 months of therapy with isoniazid—administered daily by family or twice weekly under direct observation
- 6 months of therapy with rifampin—for patients whose source case has an isoniazid-resistant, rifampin-susceptible *M. tuberculosis* strain or in patients who cannot tolerate isoniazid
- 12 doses of isoniazid and rifapentine administered weekly via direct observation for children 12 years of age and older[626]
- For children whose source case has MDR-TB, combination therapy with two drugs to which the isolate is susceptible may be considered; expert consultation should be sought

A shorter duration of effective treatment for tuberculosis infection is highly desirable to improve compliance and effectiveness.[396] In England, a 3- to 4-month course of isoniazid plus rifampin is used frequently. There

have been published case-control series, and a recent meta-analysis of available data suggests that especially when compliance is considered, a 3- to 4-month course of isoniazid plus rifampin may be as effective as is a 9-month course of isoniazid.[195] One small, randomized study also yielded favorable results with this regimen.[604] However, this regimen is not yet recommended by the CDC, AAP, or WHO.

Isoniazid preventive therapy in HIV-infected patients has been best studied in adults.[404] The theoretical advantages of this therapy in settings with high tuberculosis prevalence are that persons may be exposed without knowledge of a specific source case; HIV-infected patients may be anergic to the tuberculin skin test (and have high rates of indeterminate IGRA results); and HIV-infected persons with tuberculosis infection are at high risk for rapidly progressing to tuberculosis disease. The potential disadvantages are the potential of selecting for isoniazid-resistant isolates, inadvertently treating patients for infection when they have disease, drug toxicity in a patient who may not have infection, and cost. Randomized trials have shown IPT to be effective in preventing tuberculosis disease-free survival in adults, irrespective of the use of HAART. Isoniazid preventive therapy in HIV-infected children is controversial. Two large randomized studies have evaluated its impact on survival and tuberculosis disease-free survival in HIV-infected African children. Whereas one study showed decreased all-cause mortality and decreased cases of tuberculosis disease,[721] a second study found no benefit.[381] Additional data are needed to determine what role isoniazid preventive therapy should have in national tuberculosis programs in settings with high prevalence of both HIV and tuberculosis.

Disease in Adults

In adults, a shorter duration of antituberculosis chemotherapy is desirable for several reasons. It may be significantly less expensive than traditional therapy; the patient is exposed to potentially toxic drugs for shorter periods of time; and more time and resources can be allotted to ensure adherence with treatment. Finally, if a patient absconds from treatment, a greater likelihood will exist that bacteriologic cure already has been achieved as a result of the early and rapid sterilizing activity of the newer regimens.

A 9-month regimen of isoniazid and rifampin cures more than 98 percent of cases of drug-susceptible pulmonary tuberculosis in adults.[585] Both drugs are given daily for the first 2 weeks to 2 months. There is no difference in outcome for patients who receive medication 7 days per week versus 5 days per week. Consequently, 5 day-per-week regimens are utilized to facilitate directly observed therapy. After this, medications can be given daily, twice weekly, or thrice weekly under directly observed therapy for the remaining 7 to 8 months with equivalent results and rates of adverse reactions. When it is given twice weekly, the rifampin dose is the same as the daily dose, but the isoniazid dose is increased to 900 mg in adults. Twice-weekly and thrice-weekly administration is supported by pharmacologic and animal model data determining the area-under-the-curve characteristics for these antituberculosis drugs. Unfortunately, durations of therapy with only isoniazid and rifampin for less than 9 months are unacceptable because failure and relapse rates exceed 10 percent.

When three or more antituberculosis drugs are used initially, treatment durations of 6 months are routinely successful.[120] Regimens using isoniazid, rifampin, pyrazinamide, and streptomycin during the initial phase (2 months), followed by isoniazid and rifampin in the continuation phase (4 months), routinely yield cure rates greater than 98 percent and relapse rates below 4 percent.[25,582] If pyrazinamide is excluded from the initial phase, the rate of bacteriologic failure rises to 7 to 10 percent.[259] However, exclusion of streptomycin does not affect cure or relapse rates appreciably.[259,598] Use of pyrazinamide beyond the first 2 months of therapy does not add any benefit for patients with drug-susceptible isolates.[260] Regimens of 4 months' total duration have unacceptably high relapse rates of 10 percent or greater.[292] On the basis of all reported studies, the American Thoracic Society (ATS) and CDC currently recommend for the treatment of pulmonary tuberculosis in adults a 6-month regimen using isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by 4 months of daily or twice-weekly doses of isoniazid and rifampin.[59,92]

Duration of therapy may need to be extended in HIV-infected patients. One meta-analysis found that relapse and failure rates were higher in thrice-weekly compared with daily therapy and there was a trend toward higher relapse rates in patients who were treated for 6 months when compared with those treated for at least 8 months.[318]

Chemotherapy for Children

Clinical trials of antituberculosis drugs in children are difficult to perform, mostly because of the difficulty in obtaining positive cultures at diagnosis or relapse and the need for long-term follow-up.[611,612] Historically, recommendations for treating children with tuberculosis have been extrapolated from clinical trials of adults with pulmonary tuberculosis.[592] However, during the past 2 decades, a large number of clinical trials involving only children have been reported. In 1983, Abernathy and colleagues[2] reported successful treatment of 50 children with tuberculosis in Arkansas using isoniazid and rifampin daily for 1 month, then twice weekly for 8 months. The success rate virtually was 100 percent. Most pulmonary infiltrates cleared by the end of therapy, but hilar adenopathy usually was still present radiographically and then gradually cleared during a period of 2 to 3 years. Patients with only hilar adenopathy can be treated successfully with isoniazid and rifampin for 6 months.[287,518] In children with cavitary lung disease or children with persistently positive sputum cultures after 2 months of effective therapy, therapy may be extended to 9 months to decrease relapse rates.[99]

Several major studies of 6-month therapy in children with at least three drugs in the initial phase have been reported.* The regimen used most commonly was 6

*References 8, 53, 277, 334, 638, 651, 663.

months of isoniazid and rifampin supplemented during the first 2 months with pyrazinamide. The overall success rate has been greater than 98 percent and the incidence of clinically significant adverse reactions less than 2 percent. Regimens not using streptomycin were as successful as those that included it. Use of twice-weekly medications (under directly observed therapy) during the continuation phase was as effective and safe as was daily administration. Three studies used twice-weekly therapy throughout the treatment regimen with excellent success.[334,651,680] The 6-month, three-drug regimen is successful, tolerated well, and less expensive.[629,664] It also effects a cure faster, so the likelihood of successful treatment is greater if the child becomes nonadherent later in therapy. Current CDC and ATS recommendations are to include ethambutol with isoniazid, rifampin, and pyrazinamide during the initial phase unless the child's source case is known to have an *M. tuberculosis* isolate susceptible to first-line medications.

The optimal duration of therapy and dosing interval for antituberculous medications in children coinfected with HIV is unclear. Relapse or failure in up to 12 percent of HIV-infected children treated for 6 months has been reported.[549] The optimal timing for initiation of HAART in children with tuberculosis disease is unclear, but extrapolation from adult data suggests a survival benefit from initiation within 2 to 8 weeks.[302,571] Selection of a HAART regimen may be complicated by the known interaction of rifampin with protease inhibitors. Although these interactions are decreased by using rifabutin, some nations have deferred protease inhibitors to second-line HAART because of these interactions. Further complicating care of the coinfected child is the risk for IRIS and that children on both HAART and antituberculous medications tend to tolerate both classes of medication more poorly than children receiving one or the other.[682]

Extrapulmonary Tuberculosis

Controlled treatment trials for various forms of extrapulmonary tuberculosis are rare. In most reports, extrapulmonary cases have been combined with pulmonary cases and often are not analyzed separately. Several of the 6-month, three-drug trials in children included extrapulmonary cases.[53,334] Most non–life-threatening forms of extrapulmonary tuberculosis respond well to a 9-month course of isoniazid and rifampin[180,182] or to a 6-month regimen including isoniazid, rifampin, and pyrazinamide.[284] One exception may be bone and joint tuberculosis, which may have a high failure rate when 6-month chemotherapy is used, especially if surgical intervention has not occurred.[180] Tuberculous meningitis usually is not included in trials of extrapulmonary tuberculosis therapy because of its serious nature and low incidence. Treatment with isoniazid and rifampin for 12 months generally is effective.[685] In the 1950s, Lorber[373] treated children with tuberculous meningitis for only 6 months with good results. A more recent study from Thailand showed that a 6-month regimen that included pyrazinamide for serious tuberculous meningitis led to fewer deaths and better outcomes than did longer regimens that did not contain pyrazinamide.[288] Most children are treated initially with four drugs (isoniazid, rifampin, pyrazinamide, and ethionamide or streptomycin). Ethambutol crosses the blood-brain barrier very poorly, [161] making it a suboptimal choice for treating children with tuberculous meningitis. Treatment with pyrazinamide and the fourth drug is stopped after 2 months, and isoniazid and rifampin are continued for a total of 9 to 12 months.[166]

Drug-Resistant Tuberculosis in Children

The incidence of drug-resistant tuberculosis is increasing because of poor adherence by the patient, the availability of some antituberculosis drugs in noncontrolled over-the-counter formulations, and poor management by physicians.[55,206,207,383,464] In the United States, approximately 13 percent of *M. tuberculosis* isolates are resistant to at least one drug and 1.2 percent are MDR-TB[103]; rates of drug resistance are more than twice as high in foreign-born cases than in U.S.-born persons with disease. Initial drug resistance rates of up to 80 percent have been noted in adults with pulmonary tuberculosis in some countries,[385] and rates of 20 to 30 percent are common findings. Resistance is most common to streptomycin and isoniazid and still is relatively rare to rifampin.[148,261,429,728] Rifampin monoresistance is unusual[171]; in the vast majority of cases, rifampin resistance is seen in conjunction with isoniazid resistance. Certain epidemiologic factors—disease in an Asian or Hispanic immigrant to the United States, homelessness in some communities, and history of previous antituberculosis therapy—correlate with drug resistance in adult patients.[17,103] Patterns of drug resistance in children tend to mirror those found in adult patients in the population.[89,547,569,623] Outbreaks of drug-resistant tuberculosis in children occurring at schools have been reported.[89,523] Individual cases also have been recognized. The key to determining drug resistance in childhood tuberculosis usually comes from the drug susceptibility results of the infectious adult contact case's isolate.

Therapy for drug-resistant tuberculosis is successful only when at least two bactericidal drugs are given to which the infecting strain of *M. tuberculosis* is susceptible.[79,217,486,546,648] If only one effective drug is given, secondary resistance will develop. Exact treatment regimens must be tailored to the specific pattern of drug resistance. The duration of therapy usually is extended to at least 9 to 12 months if either isoniazid or rifampin can be used and to at least 18 to 24 months if resistance to both drugs is present.[283] Children tend to tolerate second-line antituberculosis drugs well, and community-based treatment usually is successful.[175,441] This is reflected in the lower mortality rates seen in children than in adults with MDR-TB. One pediatric series of children with MDR-TB in South Africa demonstrated 25-fold and almost 40-fold increases in mortality for children with MDR-TB and HIV coinfection and extrapulmonary tuberculosis, respectively.[562] On occasion, surgical resection of a diseased lung or lobe is required.[285,718] One meta-analysis showed that estimated success rates for pulmonary resection in adults with MDR-TB were over 80 percent,[717] a substantial improvement over the 50 to 65 percent survival seen with medical therapy alone.[474]

Treatment of a child with MDR-TB or XDR-TB exposure or infection is controversial. The benefit of preventing progression to disease, especially in a child with ongoing exposure, must be balanced against the scant pharmacokinetic, safety, and efficacy data available for many second-line medications. If resources permit, these children should be treated with two drugs to which the organism is susceptible either to complete a course of therapy for tuberculosis infection or until sequential tuberculin skin testing has been performed.[7] An expert in tuberculosis always should be involved in the management of children with drug-resistant tuberculosis infection or disease.

Adherence and Directly Observed Therapy

Nonadherence with drug treatment by patients is a major problem in control of tuberculosis because of the long-term nature of its treatment.[419,635,678] As treatment regimens become shorter in duration, adherence assumes an even greater importance. Suspected cases of tuberculosis must be reported to the local health department so that it can perform the necessary contact investigations and assist both patients and health care providers in overcoming barriers to adherence. To comply, the patient and family must know what is expected of them through verbal and written instructions in the patient's preferred language. An assessment of potential nonadherence should be made at the beginning of therapy.[36] Missed appointments should be brought quickly to the attention of the responsible public health officials, who may be able to use incentives or enablers, behavior modification, or, rarely, confinement to ensure adherence. The success of twice-weekly therapy, especially after a period of daily administration of medications, allows directly observed therapy to be given by a health care professional in cases of proven or suspected nonadherence.[107,108,284,653] Most experts hold that twice-weekly medication should be administered only under the direct observation of a health care worker.[328,699] Direct observation means that a health care worker or other nonrelated third party (e.g., teacher, school nurse, social worker) is physically present while the patient ingests the medication. A substantial number of children and their families are nonadherent with therapy. One study of isoniazid preventive therapy after tuberculosis exposure showed that 33 percent took medications for at least 4 months and only 12 percent completed a 6-month course.[211a] Adherence is inaccurately predicted by physicians. There are no documented differences in completion rates by child's age or duration of time the family has been in the United States.[504] In one study, the only factor associated with completion of tuberculosis infection therapy was health department–enabled medication administration.[133] In most communities in the United States and in an increasing number of other nations, directly observed therapy is the standard of care for all patients with tuberculosis disease.[94,196] However, when directly observed therapy cannot be used, structured behavior interactions can increase compliance with treatment.[85,651]

Summary of Treatment Recommendations

1. A regimen of isoniazid and rifampin for 6 months, supplemented with pyrazinamide during the first 2 months and ethambutol for 2 months or until the source case is known to be susceptible to all first-line agents, is standard therapy for children with suspected intrathoracic tuberculosis in the United States and Canada.
2. An alternative regimen is isoniazid and rifampin for 9 months. The disadvantages of this regimen include a longer duration, the potential for increased drug resistance during therapy, and less effectiveness if the patient absconds from treatment. This regimen should be used only if pyrazinamide cannot be tolerated.
3. After an initial 2 weeks to 2 months of daily drug administration, drugs can be given twice weekly under directly observed therapy with excellent effectiveness.[500] With patients for whom social or other restraints prevent reliable daily self-administration even during the initial phase of therapy, drugs can be given two or three times per week from the beginning under directly observed therapy.
4. In most cases, extrapulmonary tuberculosis can be treated with the same regimens as used for pulmonary tuberculosis, although data for tuberculous meningitis and bone or joint disease are relatively lacking. The duration of therapy is extended for tuberculous meningitis, osteoarticular tuberculosis, and children with substantial pulmonary disease after 6 months of therapy.[99,712]
5. Optimal therapy for tuberculosis in children with HIV infection has not been established.[630] Most HIV-infected adults with tuberculosis respond well to antituberculosis drugs but may require longer durations of treatment; higher failure and relapse rates were noted if rifamycins were used for only 6 months.[318] Immunosuppressed children with tuberculosis, including those with HIV infection, should be treated with at least three drugs initially, and treatment should be continued for a minimum of 9 months. Intermittent therapy is not recommended for HIV-infected children.[712] HIV testing is recommended for all infants and children with tuberculosis disease.
6. Tuberculosis disease occurring during pregnancy should be treated with a 9-month regimen of isoniazid and rifampin, supplemented during the initial phase with ethambutol (streptomycin should not be used). The use of pyrazinamide in pregnant patients is controversial although probably safe.

Corticosteroids

Corticosteroids have a place in the treatment of patients with tuberculosis. They should never be used except under cover of effective antituberculosis drugs. Corticosteroids would be expected to be beneficial in situations

in which the host inflammatory reaction is contributing to tissue damage or is impairing function.

Corticosteroids often are a useful addition to antituberculosis drugs if suppression of inflammatory reaction is desired, such as in the following situations[591]:

1. In patients with tuberculous meningitis in whom increased intracranial pressure is present.[658] The major actions are to reduce vasculitis, inflammation, and, ultimately, intracranial pressure. Not only is reduction of pressure desirable, but lowering of the pressure also probably favors the circulation of chemotherapeutic drugs through the brain and meninges.[200] One meta-analysis demonstrated lower rates of mortality and long-term neurologic sequelae in patients with tuberculous meningitis treated with corticosteroids than in children and adults not treated with corticosteroids.[505]
2. In patients with acute pericardial effusion in whom tamponade is occurring. Relief of symptoms takes place within hours. Use of corticosteroids reduced symptoms and mortality but not echocardiographic resolution of the effusion in both HIV-infected[234] and HIV-uninfected[633] children and adults. There appears to be a reluctance to use corticosteroids in HIV-infected patients with tuberculous pericarditis,[708] but increased mortality has not occurred when corticosteroids are utilized in conjunction with antituberculosis chemotherapy.
3. In patients with pleural effusion, a shift of the mediastinum, and acute respiratory embarrassment.[348] The long-term course probably is the same with or without corticosteroids, but symptomatic improvement usually is dramatic. One randomized trial of corticosteroid use for pleural tuberculosis in HIV-infected adults showed more rapid disease resolution, but increased rates of Kaposi sarcoma and no change in mortality, in corticosteroid recipients[192]; although both groups had similar CD4 cell counts and viral loads, no antiretroviral agents were provided, making it difficult to extrapolate the findings. Similar data are unavailable for children.
4. In patients with miliary tuberculosis if the inflammatory reaction is so severe that it produces alveolocapillary block with cyanosis.
5. In patients with enlarged mediastinal lymph nodes that are causing respiratory difficulty or a severe collapse-consolidation lesion, particularly in the middle or lower lobes, when bronchiectasis is likely to be a troublesome sequela.[453] Under either of these circumstances, a course of corticosteroids is warranted, with the realization that it will be more successful in an early infection because inflammation characterizes the first stages of tuberculosis. If caseation already is advanced, corticosteroids will be of little benefit.
6. In patients with IRIS whose reactions are either severe (e.g., airway compromise, brain stem herniation) or whose symptoms are refractory to therapy with nonsteroidal anti-inflammatory medications.[417]

The dosage of corticosteroids should be in the anti-inflammatory range, that is, prednisone 1 to 2 mg/kg/day for 4 to 6 weeks with gradual withdrawal. Some experts prefer dexamethasone, but no comparative trials have been published.

Activity

Activity need not be restricted in children with tuberculosis, except when a particular complication is inevitable (shortness of breath in pleural effusion, immobilization for a vertebral lesion).

Isolation

Isolation should be maintained for children with cavitary lesions, productive cough with acid-fast stain–positive sputum, draining sinuses, or renal tuberculosis until their secretions are negative on smear and preferably on culture. Young children are virtually noninfectious because they rarely cough and because their bronchial secretions contain few bacilli compared with those of adults with tuberculosis. Guidelines issued by the CDC state that most children with typical tuberculosis do not require isolation in the hospital.[100] Children with possible pulmonary tuberculosis should be treated as potentially infectious if they have a cavity or extensive upper lobe infiltrate, if they have a productive cough (especially if the sputum is acid-fast smear positive), or during high-risk procedures such as bronchoscopy. Although most children are not contagious with tuberculosis, the same cannot be said of their adult caregivers. Two studies in a relatively high-prevalence area of the United States showed that up to 17 percent of children admitted to the hospital for tuberculosis were accompanied by an adult with as yet undiagnosed tuberculosis.[131,445] Consideration should be given to screening caregivers of these children symptomatically or radiographically.

Follow-Up

Follow-up of children treated with antituberculosis drugs has become somewhat more streamlined in recent years. While receiving chemotherapy, the patient should be seen monthly, both to encourage regular intake of the prescribed drugs and to check, by a few simple questions (concerning appetite, well-being) and a few observations (weight gain; appearance of the skin and sclerae; palpation of the liver, spleen, and lymph nodes), that the disease is not spreading and that toxic effects of the drugs are not appearing.[701] Repeated chest radiographs should be obtained 1 to 2 months after the onset of chemotherapy to ascertain the maximal extent of disease before chemotherapy takes effect; thereafter, radiographs rarely are necessary.[324] Radiographic worsening at this time may be an indication of IRIS, the presence of drug-resistant tuberculosis, and/or adherence difficulties. Therefore, it is important to obtain this radiograph before stopping four-drug therapy and starting isoniazid and rifampin. If the radiograph at 1 to 2 months has normalized, subsequent imaging is unnecessary unless the child's disease worsens clinically. If the radiograph at 1 to 2 months is abnormal, repeating imaging at the conclusion of therapy

is helpful to reestablish a new radiographic baseline for the child. Chemotherapy has been so successful that follow-up beyond its termination is not necessary, except for children with serious disease, such as tuberculous meningitis, or those with extensive residual chest radiographic findings at the end of chemotherapy.

Case Reporting

Every case of definite or suspected tuberculosis, by United States law,[93] must be reported immediately by telephone to the health authority[216] to ensure prompt contact investigation.[265] Free antituberculosis drugs are available for diagnosed cases and for intimate contacts in almost every state of the United States and in many countries.

Prevention

Prevention of tuberculosis can be subdivided logically to consider the following circumstances:

1. Protection against exposure to the disease
2. Use of antituberculosis drugs in tuberculin-negative individuals at high risk for development of infection[559]
3. Immunization of tuberculin-negative individuals

Protection against exposure to disease is the ideal form of prevention.[398,415] It presupposes thorough preemployment and ongoing case-finding programs among all who come in contact with children, including daycare center and school personnel, Sunday school personnel, teachers, health care workers, babysitters, household servants, food handlers, beauticians, and barbers. Numerous epidemics, mini-epidemics, and mass exposures in neonatal nurseries have been traced to such infected individuals.

Immunization

Immunization against tuberculosis theoretically would be a tremendous boon to humanity, but in practice it has been fraught with very great difficulty. Various strains of mycobacteria and diverse nonliving immunogenic fractions have been studied. The impossibility of standardizing vaccines in the early days, the lack of any clinically useful test reflecting the immune status of the individual, and the relatively slow course of the disease have handicapped epidemiologic studies. A number of new vaccines are in human clinical trials. These studies use surrogate markers of interferon, interleukin, and other cytokine responses as measures of vaccine take, because finding correlates of protection remain elusive.[242,560]

BCG was developed at the Institut Pasteur in Paris by Calmette and Guérin, who, starting in 1908, made 231 passages of a strain of *M. bovis* on a beef bile medium, thereby producing marked attenuation. Injected into laboratory animals, this strain was shown to increase resistance to challenge with virulent *M. tuberculosis*. In 1921, it first was administered orally to neonates and since then has been given to more than 4 billion people.

BCG vaccine attempts to replace the potentially dangerous primary infection with *M. tuberculosis* with an innocuous primary infection with the bacillus of Calmette and Guérin, thus activating host cell-mediated immunity with minimal chance of causing progressive disease so that an infection with *M. tuberculosis* will be of the "reinfection" type.[365]

Variations in strains and lack of standardization are basic problems in evaluating the results of immunization.[49,223,649] BCG was maintained for many years by serial passage at the Institut Pasteur and distributed to hundreds of laboratories all over the world. Not until 1966 did the WHO Expert Committee on Biological Standardization adopt formal requirements for the maintenance of frozen "seed lots" to minimize the inevitable mutations that have produced BCG vaccines with widely varying characteristics. Routine quality control measures carried out by the production laboratory include an identity test, a test for contamination, a safety test in guinea pigs, an estimate of the total bacillary mass, viability, and a test of heat stability. Periodic assessment of the allergenic capacity in humans is part of quality control testing. The WHO, through its International Reference Preparation for BCG vaccine and through quality control testing, has helped decrease the gross variations in BCG vaccine found until recent years.

Vaccination techniques and dosages are variable. Intradermal injection is the most precise technique. Multiple-puncture techniques are popular because they are easy, but reported results consistently are inferior to those obtained with intradermal injection. Oral vaccination, the original method of administration, largely has been abandoned because of poor results. The actual dose of BCG at present usually is approximately 10^6 culturable particles. Because in animals large doses produce better resistance to challenge than small ones do, the largest convenient dose is used. However, in neonates, who have a higher incidence of untoward reactions, the customary approach is to halve the dose generally used in older infants and children to prevent local complications.

The usual local reaction to intradermal BCG vaccine is the development of a papule at the site of vaccination, and this papule reaches its maximal diameter (10 to 20 mm) in the sixth week. A small crust that may form on the papule detaches at about this time, with only a small ulcer remaining that may discharge a surprising amount of pus. Most ulcers are healed by the 10th week. A small scar is visible in over 80 percent of BCG-vaccinated individuals.[319,540] Enlargement of the regional lymph nodes occurs regularly and is painless, sometimes ending in calcification. Formation of an abscess with breakdown is a rare event, but it occurs more often in infants.

Untoward reactions to BCG rarely have been a problem.[666] Fatalities caused by progressive disease have been reported in no more than 60 vaccine recipients (of an estimated 3+ billion), usually (but not always) children with well-documented immunodeficiency.* No return of the attenuated strain to virulence has ever been noted. In countries where BCG is used routinely for immunization of neonates, osteomyelitis has been diagnosed in some 5

Brazil: schoolchildren†	Pereira et al., 2011	1996-1998	Moreaux	9	25

*The initial estimate of efficacy was 60 percent. Subsequently, when follow-up was extended to 9 to 14 years, the efficacy figure declined to 31 percent.
†BCG vaccine given for the first time to children 7 to 14 years of age.
Modified from Sutherland, quoted by Eickhoff TC. The current status of BCG immunization against tuberculosis. *Annu Rev Med* 1977;**28**:411–23.

per 100,000 neonates. It usually becomes manifested when the child is between 5 and 33 months of age, when a tender swelling is noted near a joint; bone destruction is well localized and responds to conservative treatment.[106] On the whole, BCG is one of the safest vaccines in use.

In many countries where BCG is given routinely, the incidence of HIV infection in adults and children is high.[71,529] Reports of local and systemic complications from BCG vaccine in HIV-infected people are increasing, but the true magnitude of the interaction is not yet known.* However, in more recent studies, the rate of adverse BCG reactions in HIV-infected children appears to be higher than thought previously.[248,249] In most cases, BCG complications occur shortly after vaccination, but in one man with AIDS, adenitis as a result of BCG occurred 30 years after inoculation.[520] Routine treatment of patients with previous BCG vaccination who subsequently become immunocompromised is not recommended, but the clinician should be aware of previous BCG vaccination if signs or symptoms of mycobacterial infection occur.

The efficacy of BCG vaccines in humans has been evaluated in several large, well-controlled studies (Table 96-11). Three of these trials showed excellent protection, two showed mediocre protection, and two showed little or no effect of BCG. Another study, not tabulated because its numbers are relatively small, is the "experiment of nature" reported by Hyge[276] in 1957. Hyge[276] observed an epidemic of tuberculosis in a school for girls, in which 105 girls initially were tuberculin negative, 130 were tuberculin positive, and 133 were BCG immunized. In this group, the total incidence of tuberculosis was 23 times as high in the tuberculin-negative girls as in the BCG-immunized girls. Explanations for these differences in outcomes among trials must be sought in the quality and characteristics of the BCG vaccine used in the particular trial, the possible immunizing effect (in Georgia and Alabama) of infections with other mycobacteria,[589] the possibly greater effectiveness of BCG vaccine in areas of high tuberculosis prevalence, and methodological variations among the trials.

The most recent large study of BCG effectiveness is the Chingleput study, started in 1968 in Chingleput District near Madras, South India, an area where sensitization with nontuberculous mycobacteria is prevalent. People of all ages were vaccinated with one of two BCG vaccines or a placebo; only the incidence of adult-type pulmonary tuberculosis in the three groups was compared (i.e., not the forms usually found in children). During the ensuing years, no difference in incidence was noted among the three groups.[24] This disturbing result has been the subject of several WHO investigations because BCG is one of the vaccines recommended for all children in the Expanded Program of Immunization sponsored by the WHO itself.[519] Another study of neonatal vaccination with BCG in England reported very favorable results with BCG.[137] Most countries administer BCG to infants. In some nations, multiple doses of BCG are used. The few data that are available on revaccination show a modest efficacy (9%).[33,526] Revaccination with BCG is not recommended by the World Health Organization. Higher effectiveness (up to 25%) is seen when BCG is given to school-aged children who never received BCG as infants.[499]

A group at the Harvard School of Public Health reviewed all published studies of BCG efficacy in a meta-analysis.[122] Most published trials were not analyzed because of serious flaws in their experimental design or reporting. Among all trials and case-control studies included, the average protection against tuberculosis disease by various BCG preparations was 50 percent. The

*References 47, 248, 249, 467, 517.

protective levels were higher for disease in children, particularly for meningitis and tuberculosis-associated death.[121,662] However, ascertainment bias and lack of standardized case definitions render the results of these analyses very difficult to interpret. The BCG vaccines prevent many cases of tuberculosis in children, but the effect is quite variable. Variation in effectiveness of BCG in pulmonary tuberculosis has been seen across a number of trials. It has been hypothesized that these differences may be due to differences in BCG strains, overattenuation of BCG strains, interference in immunologic response caused by nontuberculous mycobacteria, and polymorphisms seen in human populations.[316] That BCG vaccines are not an instrument of tuberculosis control also has become apparent because they do not prevent infection with *M. tuberculosis*, their protective effect is short lived, and vaccination of infants does little to prevent future cases of contagious tuberculosis among adults in a community.

The role of BCG vaccine in the United States today is very limited. The Advisory Committee on Immunization Practices of the U.S. Public Health Service and the Advisory Council for the Elimination of Tuberculosis recommend BCG only for tuberculin-negative infants and children in the United States who (1) are at high risk for having intimate and prolonged exposure to persistently untreated or ineffectively treated adults with infectious pulmonary tuberculosis, cannot be removed from the source of infection, and cannot be prescribed long-term preventive therapy or (2) continuously are exposed to people with tuberculosis resistant to isoniazid and rifampin.[95] A few experts, however, are more inclined toward the use of BCG in neonates who are at any risk for exposure to tuberculosis whatsoever.[310,311,583,659]

Contraindications to the use of BCG for prevention of tuberculosis include congenital immunodeficiency, known HIV infection (in the United States), leukemia, lymphoma, and generalized malignant disease as well as treatment with corticosteroids, alkylating agents, antimetabolites, and radiation. The WHO recommends giving BCG to asymptomatic HIV-infected infants who reside in areas with high tuberculosis rates.

CHAPTER 97

Other Mycobacteria

W. Matthew Linam • Richard F. Jacobs

The definition of mycobacteria other than tubercle bacilli is quite confusing. Runyon[156] in his address to the International Conference on Atypical Mycobacteria probably defined them best: "Tubercle bacilli include *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium africanum*. Together with *Mycobacterium microti* (not pathogenic for humans), these organisms constitute the tubercle bacillus complex." Any mycobacteria not listed in this group are considered to be in the "other" grouping. Mycobacteria other than those causing tuberculosis and leprosy were not recognized as causes of disease in humans until the 1950s.[189] The incidence of disease caused by these organisms remained stable until the acquired immunodeficiency syndrome (AIDS) epidemic began in the 1980s. The most common forms of the disease are chronic pulmonary disease resembling tuberculosis (occurring mainly in adults), cervical adenopathy in children, skin and soft tissue infection, and disseminated disease in immunocompromised individuals.[135] In the mid-1980s, the incidence of infections with nontuberculous mycobacteria (NTM) increased markedly, probably because of the increased number of immunocompromised patients (e.g., because of AIDS and organ transplantation) and the significant improvement in microbiologic methods for cultivating these organisms.[216,221]

EPIDEMIOLOGY

NTM are ubiquitous in nature. They are found in soil, water, animals, milk,[50] and food. Of importance in some hospital-acquired infections or infections in immunocompromised hosts is the presence of the organisms in common tap water.[18,70,121,182] Exposure to environments, especially soil, colonized by these organisms seems to be important for acquisition of disease in children. Organisms commonly found in soil include *Mycobacterium scrofulaceum*, *Mycobacterium flavescens*, *Mycobacterium avium* complex (MAC), *Mycobacterium gastri*, *Mycobacterium terrae*, *Mycobacterium fortuitum*, and *Mycobacterium chelonae*. Water is an important source for all of the previously named organisms and for *Mycobacterium kansasii*, *Mycobacterium marinum*, *Mycobacterium gordonae*, and *Mycobacterium xenopi*.

In contrast, humans are the only known reservoirs for *M. tuberculosis*. In a survey from the Centers for Disease Control and Prevention (CDC), 35 percent of mycobacteria isolated in laboratories were nontuberculous.[63] MAC (*Mycobacterium avium* and *Mycobacterium intracellulare*) accounted for 66 percent of the nontuberculous isolates, followed by *M. fortuitum* (19%), *M. kansasii* (9%), and *M. scrofulaceum* (6%). These data were collected in 1980, before the present AIDS epidemic and before the rapid increase in the number and types of immunocompromised patients; therefore, current rates probably are much higher. Two studies from 2009 showed a similar distribution of nontuberculous isolates. The distribution in the Australian study was MAC (48.5%), *Mycobacterium abscessus* or *M. chelonae* (13.2%), *M. fortuitum* (11.8%), and *Mycobacterium ulcerans* (5.9%).[15] The distribution in a California study was MAC (47%), *M. abscessus* or *M. chelonae* (22%), and *M. fortuitum* (5%).[150] Some of the variation seen may be due to geographic differences.

Geography apparently has some bearing on the prevalence of these infections. The southeastern part of the United States has much higher rates of infection in children than does the Northeast or the Northwest. MAC was seen most commonly along the coastal borders of the United States and in the states bordering Canada. The highest rates were seen in Hawaii (10.9/100,000 population), Connecticut (8.9 cases per 100,000 population), and Florida (8.4 cases/100,000 population). High rates also were seen in Kansas and the desert Southwest, however, showing the widespread nature of this organism in causing disease. In contrast, *M. kansasii* was seen most commonly in the Midwest of the United States and almost never in the Southeast.[53] States with rates of *M. kansasii* greater than 0.75/100,000 included Missouri, Illinois, Kentucky, Indiana, Kansas, Nebraska, Louisiana, Texas, Arizona, and Florida. North Carolina, a state with one of the highest rates of MAC (>4.8 cases/100,000 population), had few cases of *M. kansasii* (0 to 0.25/100,000 population). *M. marinum* frequently was isolated from coastal areas, whereas *M. xenopi* was scattered across the United States, with 50 percent of cases found in just three states (Connecticut, Wisconsin, and California). Internationally, incidence rates of NTM infections in children range from 0.84/100,000 (Australia) to 3.1/100,000 (Germany).[15,149] For all of the nontuberculous species, males and rural residents had a much higher incidence of infection.[162] Extrapolation of these rates to determine disease patterns is not without problems, however. The number of mycobacterial isolates could be skewed easily by the presence of multiple isolates from a single patient, or it may just represent colonization. Nonetheless, these rates can help predict which species of NTM are most likely to be encountered in a particular geographic region while the physician awaits final identification and sensitivity testing on an isolated nontuberculous organism.

The site of isolation from the human source can be helpful in determining the type of mycobacteria that may be involved in the disease process. MAC is responsible for lymphadenitis, particularly in children. MAC also is responsible for pulmonary disease and disseminated disease to bones and occasionally to the meninges. *M. kansasii* is associated most commonly with infections of pulmonary origin and disseminated lesions in adults; rarely, it is associated with adenitis and skin granuloma in children. *M. scrofulaceum* also causes lymphadenitis in children, and *M. marinum* is responsible for skin granuloma and ulcers after exposure to certain salt water beaches, swimming pools, and tropical fish tanks. The rapidly growing mycobacteria, such as *M. fortuitum* and *M. chelonae*, often cause skin and soft tissue infection and, rarely, pulmonary and disseminated disease in adults and children. A notable exception is the rapidly growing mycobacterium *M. abscessus*, which is the third most common NTM species recovered from respiratory specimens.[68] Health care–associated NTM infections have been reported in patients with long-term vascular catheters, peritoneal dialysis catheters, and various surgical procedures. Rapidly growing mycobacteria are frequently implicated. The source is often contaminated tap water.

A familial immune defect predisposing to disseminated NTM infection in childhood has been reported.[109] Interleukin (IL)-12 and interferon (IFN)-γ play an important role in the control of mycobacterial infections, primarily through upregulation of tumor necrosis factor (TNF)-α. Defects in either the synthesis or signaling pathways of these cytokines have resulted in disseminated NTM infections.[48] In addition, patients receiving anti–TNF-α therapy may be at increased risk for NTM disease, especially if they are receiving additional immune suppressive medications.[214]

MICROBIOLOGY

Runyon and Timpe[154,155,189] in their monumental work on NTM suggested a useful classification system based on three characteristics of the organisms: production of pigment, rate of growth, and colonial characteristics. The four groups are as follows: group I—photochromogens, which produce bright yellow to red pigment in the presence of light; group II—scotochromogens, which produce yellow to orange pigment in the dark; group III—nonphotochromogens, which are non–pigment producers; and group IV—rapid growers, which generally grow in less than 1 week. Kubica[100] published an updated version of Runyon's classification in 1978, and it was useful for many years. Subsequently, a more "simplified" classification based on the growth rates of the organisms alone was proposed.[216] More recently, reliable DNA sequencing, using the highly conserved *16S rRNA* gene, has allowed for rapid recognition of new species. A sequence difference of greater than 1 percent usually indicates a new species. Currently, 154 NTM species have been identified.[55,125,191]

The NTM still are differentiated by most clinical laboratories based on various morphologic, physiologic, and biochemical characteristics (Tables 97-1 and 97-2). The difficulty with identifying many of these organisms is their slow growth rates with standard techniques. Because antibiotic susceptibility varies for different nosocomial tracheobronchitis (NTB), it is important to identify organisms to the species level to ensure the appropriate therapy is chosen.[69] Beginning sensitivity testing as soon as an organism is cultivated and thought to be the responsible pathogen is useful because several months may be required for proper identification and susceptibility testing. Serologic tests can be helpful in identifying some

TABLE 97-1 **Characteristics of Slow-Growing Pathogenic Mycobacteria**

of the organisms.* In clinical medicine, however, they rarely are valuable for establishing a diagnosis in an individual patient. A study using humoral immunoglobulins against mycobacterial antigens failed to diagnose tuberculosis or nontuberculous adenitis in children.[196] Blood cultures for mycobacteria are best performed with the Isolator lysis-centrifugation system or the radiometric BACTEC 13A blood culture bottle.[2,92,93] Blood collected in ethylenediaminetetraacetic acid or coagulated blood is unacceptable. Body fluids such as cerebrospinal fluid, pleural fluid, and peritoneal fluid can be inoculated directly into BACTEC or Septi-Chek broth, particularly if only small volumes are available. To aid in detection and growth, cultures should include both solid and broth media, whenever possible. Gene probes became commercially available in the late 1980s. They involve DNA probes complementary to species-specific sequences of rRNA for the identification of *M. tuberculosis*, MAC, *M. gordonae*, and *M. kansasii*.[65]

Polymerase chain reaction (PCR) assay has been evaluated for the routine detection of *M. tuberculosis* in the clinical laboratory and compared with fluorochrome smear and culture. Multiplex, real-time PCRs also have been developed to aid in the rapid identification of NTM. In a study by Kim and colleagues,[97] a multiplex, real-time PCR was developed capable of identifying 23 mycobacterial species and was tested using 77 reference strains and 369 clinical isolates. The test correctly identified all 189 (100%) isolates of the *M. tuberculosis* and 169 (93.9%) of the NTM isolates. Another multiplex, real-time PCR test using 314 clinical isolates had a 95 to 99 percent sensitivity and 99 to 100 percent specificity for distinguishing *M. tuberculosis* complex, MAC, the *M. chelonae–M. abscessus* group, the *M. fortuitum* group, and *Mycobacterium mucogenicum*.[150] The PCR testing offered by commercial laboratories at present is not approved by the U.S. Food and Drug Administration for in vitro diagnosis.

MANIFESTATIONS OF NONTUBERCULOUS MYCOBACTERIAL INFECTION IN CHILDREN

Lymphadenitis

Lymphadenitis is the most common manifestation of NTM infection in children. It also can occur rarely in adults.[44,105,113] All nodes in the cervical chain can be affected, but the nodes of the submandibular region seem to be most commonly involved.[46,119] The parotid gland also can be affected.[39] The differential diagnosis frequently centers on deciding whether a malignant process or a nonmalignant process is present. Nonmalignant processes to consider include mononucleosis, bacterial adenitis, cat-scratch disease, toxoplasmosis, tularemia, and *M. tuberculosis* infection.

Most mycobacterial cases of lymphadenitis are caused by the nontuberculous organisms. The clinician also must consider the possibility of *M. tuberculosis*, however.[35] No clinical features help the clinician discern between NTM infection and tuberculosis. The use of histopathology has been postulated to help differentiate between atypical and tuberculous infections.[140] In a retrospective study, the findings of ill-defined (nonpalisading) granulomas, irregular or serpiginous granulomas, a predominantly nonspecific granulomatous response, predominantly sarcoidlike granulomas, or lack of significant caseation were seen more commonly with nontuberculous lymphadenitis. Additionally, nontuberculous infections had neutrophils predominantly in the center of the necrosis, whereas in tuberculous infections, neutrophils were scattered throughout the specimen.[140] A prospective study investigating these findings has not been published to date, and other authors have not noted similar patterns.[12]

In a Canadian study, the rate of NTM as a cause of lymphadenitis was 1.21 cases/100,000 children, whereas the rate for tuberculosis was 0.3 case/100,000 children.[171] Investigators from San Diego reported a marked increase in the number of infections in children.[141] Other authors around the world have reported a markedly increased incidence of infection with these organisms in immunocompetent children.[61] In one study, the incidence increased from 1 case between 1987 and 1990 to 85 cases between 1991 and 1993.[104] In a large study compiled by Lincoln and Gilbert[112] involving 243 children, more than 50 percent were younger than 3 years of age and 80 percent were younger than 5 years. In contrast, one study showed that the mean age had increased to 5.2 years.[210] More recently, a Canadian study compared the incidence of NTM cervicofacial adenitis in children from 1994 to 1998 (25.1/100,000 hospitalizations) and 1999 to 2004 (107.4/100,000 hospitalizations) and showed a statistically significant increase. Contact with NTM sources such as soil and water may account for the frequency of cervical lymphadenitis in young children.[193]

Most patients have no systemic symptoms and exhibit normal chest radiographs; other laboratory studies generally are not helpful. The mean duration of swelling is approximately 6 weeks. Affected lymph notes are often unilateral and nontender. Over time, NTM infections involving superficial lymph nodes may develop a violaceous discoloration of the overlying skin. Nodes may spontaneously rupture or develop draining sinus tracts.

*References 42, 101, 154, 195, 203, 216, 218, 221.

Infections are caused mainly by MAC and *M. scrofulaceum*. A large prospective study spanning 32 years from 1958 to 1990 showed that MAC has become the predominant etiologic agent and has surpassed *M. scrofulaceum* from earlier in the study.[219] Current data estimate that 72 percent of NTM lymphadenitis cases are caused by *M. avium*.[139] A series of 190 patients from India showed, however, that 60 percent of the nontuberculous adenitis cases were caused by *M. scrofulaceum*, followed by 40 percent by *M. avium-intracellulare*.[88] This difference may be due in part to differences in water chlorination. Case reports involving *M. fortuitum* also have been published.[151] Lymphadenitis caused by *Mycobacterium haemophilum* is being diagnosed in immunocompetent children in increasing numbers.[8,159] Samra and colleagues[159] showed that the BACTEC radiometric system or MB Redox broth is superior to Löwenstein-Jensen media for isolation of *M. haemophilum*. This organism is thought to have been underdiagnosed previously because of the widespread use of Löwenstein-Jensen media. *M. malmoense* also has been described as an etiologic agent of cervical lymphadenitis in children.[192] Haas and associates[73] described *Mycobacterium heidelbergense*, a new agent of mycobacterial lymphadenitis in children.

Currently, no NTM skin test is commercially available in the United States. All patients with suspected NTM lymphadenitis should have a tuberculin skin test placed. Children with NTM lymphadenitis can have a variety of reactions to tuberculin skin tests, ranging from 0 mm to greater than 10 mm of induration. Needle aspiration of an affected node can be a valuable diagnostic tool. Cultures for bacterial and mycobacterial etiologies should be performed, with recovery rates in children with cervical lymphadenitis ranging from 60 percent to 88 percent.[10,16,81,91,224] The aspirate should be inoculated onto aerobic and anaerobic media and Sabouraud agar and mycobacterial media (Löwenstein-Jensen slants or Middlebrook media). Use of the BACTEC system can be helpful, especially in isolation of more fastidious species. Mycobacteria can be isolated 12 to 17 days after inoculation.[176] More recently, preoperative diagnosis of *M. avium* lymphadenitis was accomplished with the use of PCR of gastric aspirates in two children.[72] PCR is being used with increasing frequency in the diagnosis in NTM lymphadenitis.[31,139]

The best treatment of lymphadenitis caused by NTM is complete excision of the involved lymph node.[120,200] Incision and drainage without excision results in a high rate of secondary drainage, and subsequent excision of the remaining tissue is required for cure.[5,158,165] Complete excision may not be possible when affected nodes are adjacent to large vessels or the facial nerve. In those situations, adjunctive antibiotic therapy may be necessary. The majority (59%) of clinicians manage NTM lymphadenitis by surgical excision followed by adjunctive antibiotics.[139] A randomized controlled trial involving 100 children with NTM cervicofacial lymphadenitis compared surgical excision to antibiotic therapy with clarithromycin and rifabutin.[114] Esthetic outcome was significantly better in the surgical group. Another small study showed successful nonsurgical management of deep cervical NTM lymphadenitis.[75]

Acquired Immunodeficiency Syndrome and Nontuberculous Mycobacteria

Before the availability of highly active antiretroviral therapy (HAART), NTM infections, most commonly MAC, were the second most common opportunistic infections in children in the United States with human immunodeficiency virus (HIV) infection. The incidence rate in the pre-HAART era was 1.3 to 1.8 episodes per 100 person-years.[62,133] Approximately 6 percent of adults and 4 percent of children with AIDS reported to the CDC had disseminated MAC infection as the AIDS-defining disease.[22] Autopsy studies show that MAC infection is present in 20 percent to 50 percent of adult HIV-infected patients.[147,208,212] In a retrospective study from 1990 to 1996 in New York City, 26 percent of children had evidence of MAC infection at the time of their deaths.[89] MAC infection was thought to be the cause of death in 13 percent of the 54 children with HIV infection, and the mean age at death was 7.8 years. In two autopsy studies of opportunistic infection in HIV-infected children in Latin America and Argentina, 2.7 percent and 3.4 percent, respectively, had evidence of disseminated disease.[49,144] In these studies, 62 percent (Argentina) and 72 percent (Latin America) of the children studied were younger than 1 year of age. These data indicate that MAC infection is seen less commonly in younger children with HIV. Since the availability of HAART, incidence of MAC has decreased to 0.14 to 0.2 episodes per 100 person-years.[62,133]

In the CDC study, MAC was the NTM most commonly isolated. *M. kansasii* and *M. scrofulaceum* were found in one case each. In adult studies, the incidence of infection with *M. kansasii* and *M. scrofulaceum* also is low.[45,84] In patients with HIV, *M. fortuitum* complex is the most frequently isolated rapidly growing mycobacteria and typically causes lymphadenitis and pulmonary disease.[145] More than 70 percent of children with MAC and AIDS had evidence of disseminated disease. Almost all had $CD4^+$ counts less than 100 cells/mm^3. Clinical findings included failure to maintain growth curves, anorexia, persistent or recurrent fever, fatigue, and abdominal pain. MAC has been shown to infect the esophagus, stomach, and intestine of pediatric patients with AIDS.[90] Patients with extensive MAC infection of the small and large intestines have severe, persistent diarrhea. Respiratory symptoms are uncommon. Clinical findings may include hepatomegaly, splenomegaly, or lymphadenopathy. Bone marrow suppression also may occur. The median age at diagnosis was 46 months, with a median of 9 months elapsing between the onset of symptoms and positive cultures. When NTM infection was diagnosed in these patients, they survived less than 10 months. Blood cultures have 90 percent to 95 percent sensitivity in detecting disseminated MAC infection in adult patients with AIDS.[76] Infection is also confirmed by isolation of MAC from a normally sterile body site such as lymph node or bone marrow.

Mycobacterium genavense has been shown to cause infection in children with HIV infection.[132] The children were febrile and had abdominal cramps and diarrhea. $CD4^+$ lymphocyte counts were less than 400/mm^3. The

organism was found in numerous stool samples and lymph node specimens. Multiple-drug regimens that include amikacin, ethambutol, rifampin, and clarithromycin may be useful in treating this infection.

For treatment of MAC infection in HIV-infected children, combination therapy is recommended.[127] Clarithromycin 15 to 30 mg/kg/day divided twice daily (maximum 500 mg) or azithromycin 10 to 12 mg/kg once daily and ethambutol 15 to 25 mg/kg/day in a single dose (maximum of 2.5 g) should be included. Additionally, the use of rifabutin 10 to 20 mg/kg/day once daily (maximum 300 mg) or ciprofloxacin 20 to 30 mg/kg/day divided twice daily intravenous or orally (maximum 1.5 g) can be considered. The use of granulocyte colony-stimulating factor as an adjunct to antimicrobial therapy for disseminated MAC infection has been reported,[136] but additional data are needed to determine the usefulness of this agent. Immune reconstitution inflammatory syndrome has been reported in adults and children with MAC infection receiving HAART.[37,167]

Secondary prophylaxis is recommended for all children with a history of disseminated MAC infection. Clarithromycin 7.5 mg/kg orally in two doses (maximum 500 mg) is recommended in combination with ethambutol 15 to 25 mg/kg/day once daily (maximum 2.5 g), with or without rifabutin 5 mg/kg/day once daily (maximum 300 mg). In most situations, secondary prophylaxis is lifelong. Guidelines are available for discontinuing prophylaxis in children who have completed appropriate therapy, are without evidence of ongoing infection, are stable on HAART, and have sustained recovery of their $CD4^+$ cells above the threshold for initiating primary prophylaxis.[127]

The use of clarithromycin 7.5 mg/kg orally twice daily (maximum 500 mg) or azithromycin 20 mg/kg once weekly (maximum 1.2 g) for prophylaxis is recommended for adults and children with advanced immunosuppression. The U.S. Public Health Service and the Infectious Disease Society of America have published guidelines for the prevention of opportunistic infections, including disseminated MAC.[127] These guidelines incorporate age-specific $CD4^+$ counts at which prophylaxis should be used: children 6 years of age or older, fewer than 50 cells/mm^3; children 2 to 6 years old, fewer than 75 cells/mm^3; children 1 to 2 years old, fewer than 500 cells/mm^3; and children younger than 1 year, fewer than 750 cells/mm^3. Before initiating prophylaxis, patients should be evaluated for disseminated MAC infection by obtaining a blood culture for MAC. In HIV-infected children older than 2 years of age, primary prophylaxis may be discontinued once they are stable on HAART (>6 months) with sustained immunologic response for over 3 months (children 6 years of age or older, >100 cells/mm^3; children 2 to 6 years old, >200 cells/mm^3). A phase I/II study of prophylactic rifabutin for prevention of disseminated MAC infection in children showed a side effect of bilateral, stellate corneal deposits without associated uveitis in 6 of 25 children.[173]

The emergence of resistance is a concern with the MAC prophylactic regimens in patients with AIDS. In some trials, 9 percent of adults receiving azithromycin prophylaxis and 5 percent of adults receiving clarithromycin prophylaxis had breakthrough MAC bacteremia. Of these cases, 11 percent and 58 percent of the azithromycin and clarithromycin, respectively, breakthrough isolates were macrolide-resistant.[6,77]

Pulmonary Infections

Reviews from the late 1970s showed that pulmonary disease caused by NTM usually was caused by *M. kansasii* and MAC.[32,64,152] MAC infection most commonly occurred during the sixth decade, whereas *M. kansasii* infection occurred in individuals a decade younger. Men were affected most commonly, in ratios as high as 4:1. Chronic obstructive pulmonary disease (COPD) as noted by radiographic findings was found in 50 to 60 percent of patients with NTM pulmonary infections. Bullous lung disease was seen in 24 to 39 percent. The lobar distribution and severity of disease were similar for NTM agents and *M. tuberculosis*, with one exception—*M. kansasii* was much more prone to producing unilateral disease, which occurred nearly 60 percent of the time in contrast to 35 percent of the time in MAC or *M. tuberculosis* infection. Typically, disease begins in the posterior portions of the upper lobes. Progression to cavitary disease occurred in 87 percent of patients with *M. tuberculosis* and MAC infections and in 96 percent of patients with *M. kansasii* infection. Rare case reports of mediastinal mass lesions in children caused by NTM have been published.[56]

Two recent prevalence studies have shown that the epidemiology and clinical features have changed. An Oregon study estimated the 2-year prevalence of NTM pulmonary disease to be 8.6 cases/100,000 persons (20.4/100,000 for persons older than 50 years).[215] In a large multisite study, the age-adjusted annual prevalence was 5.4 cases/100,000 persons.[142] Both studies show an increased prevalence of NTM pulmonary disease. This increase is most evident in women, especially those older than 60 years of age.[142] MAC was the most common isolate (80% to 87.5%), followed by *M. abscessus* or *chelonae* (6% to 12%).[142,215] Other species causing NTM pulmonary disease include *Mycobacterium simiae*, *M. kansasii*, *M. fortuitum*, *M. mucogenicum*, and *M. xenopi*.[142] Underlying comorbidities such as COPD, bronchiectasis, and lung cancer were common, with bronchiectasis more common in women.[142,215] Most common imaging findings were nodules (59%), bronchiectasis (39.7%), and cavitary lesions (8.5%).[142] NTM pulmonary disease is uncommon in children and most frequently seen in children with cystic fibrosis.[38]

Patients with cystic fibrosis have been noted to have an increased incidence of infection with NTM. Prevalence rates of 2 to 20 percent have been reported.[4,79,80,95] A large multicenter prospective prevalence study of NTM in patients with cystic fibrosis from France included 1582 patients.[153] The prevalence of patients with at least one positive NTM culture was 6.6 percent. The prevalence of patients meeting criteria for NTM infection was 3.6 percent. *M. abscessus* complex and MAC were the most common species responsible for both colonization and disease. Mycobacterial infections are seen more commonly in older patients with cystic fibrosis. The peak

prevalence for *M. abscessus* was 11 to 15 years and 25 years for MAC.[153] Frequent intravenous antibiotic use is a possible risk factor for colonization with NTM.[190] *M. abscessus* has emerged as a clinically persistent pathogen in patients with cystic fibrosis, especially patients on steroid therapy for allergic bronchopulmonary aspergillosis.[54,131,190] Persistent *M. abscessus* infection has been associated with lung function decline.[53] Other organisms cultured from patients with cystic fibrosis include *Mycobacterium peregrinum*, *M. kansasii*, *M. fortuitum*, *M. chelonae*, and *M. xenopi*. Bacterial contamination, particularly with *Pseudomonas aeruginosa*, of the acid-fast bacilli cultures from patients with cystic fibrosis has been a major problem that has rendered isolation of mycobacteria more difficult.[174] Another confounding problem is the difficulty in differentiating infection from colonization in these patients.[95]

The American Thoracic Society recommends radiographic changes (i.e., nodules, cavitary opacities, or multifocal bronchiectasis), isolation of multiple colonies of the same species, and the absence of other potential pathogens as criteria for the diagnosis of pathogenic infection with NTM.[3] Discernment is even more difficult in the setting of the chronic lung disease seen in patients with cystic fibrosis. Kilby and associates[95] suggest that repeated isolation of NTM associated with pulmonary cavities or infiltrates that do not improve with aggressive standard antibacterial treatment could indicate active mycobacterial disease in patients with cystic fibrosis.

Treatment of NTM pulmonary disease recommended by the American Thoracic Society requires prolonged courses using multidrug regimens. Drugs are administered for 18 to 24 months, with a minimum of 12 months of culture negativity required while receiving therapy. Treatment of MAC pulmonary infections involves clarithromycin or azithromycin, ethambutol, and rifampin. In fibrocavitary or other severe disease, streptomycin or amikacin may be added.[69] Treatment success is variable. The median efficacy of macrolide-based regimens reported in a recent review of 12 clinical trials was 56 percent (range, 26% to 71%).[57]

M. xenopi has been described in adults as a cause of infection of the pulmonary tract.[172] The mean age at infection was 62 years, and it occurred in a mainly Canadian population. Eighty-six percent of the patients had underlying pulmonary pathology, including COPD, previous pulmonary tuberculosis, carcinoma of the lung, sarcoidosis, and cystic fibrosis. Additionally, a case was reported of a 7-year-old boy with leukemia in whom pneumonia with *M. xenopi* developed and was treated successfully with 2 years of therapy that included ethambutol and clarithromycin.[108]

M. simiae has been isolated in adults with underlying pulmonary abnormalities.[11,99] *M. simiae* is the most drug-resistant of all the NTM. Some isolates are resistant to all drugs tested.

Mycobacterium szulgai has been described in several case series as a cause of lung disease.[118,206] Disease occurred in elderly white men and resembled chronic tuberculosis. Therapeutic regimens effective against *M. avium* seemed to provide good clinical outcomes.

Skin Infections

Mycobacterium marinum

M. marinum is photochromogenic and was identified as a pathogen in fish in 1926 by Aronson.[112] Skin lesions usually result from light trauma (abrasions) in swimming pools or other bodies of water when the surfaces of the pool are colonized by *M. marinum*.[41,128] Fish tanks also have been implicated and generally involve the upper limb or a finger.[9,186] Most cases occur in children aged 10 to 16 years old. The most common sites are the elbows, knees, and ankles. Cooler superficial portions of the body are affected most frequently. Other exposed body areas can be involved, depending on what part of the body has made contact with the water containing the mycobacterium (e.g., the nose in divers).[129] Lesions are usually solitary but may have a sporotrichoid pattern. Regional spread of lesions has been reported.[179]

The incubation period from exposure to formation of a small, indurated papule that ulcerates generally is 3 weeks. The lesion then crusts and forms a granuloma with a small crater. The lesions usually are painless and resolve in several months; occasionally, they can last longer. In contrast to other mycobacterial diseases, regional nodes are usually not involved.

Infection with this organism usually is benign. A main consequence, however, is that patients with *M. marinum* infection frequently have conversion of their purified protein derivative stabilized with Tween (PPD-T) test to positive.[112] The natural reservoir for *M. marinum*, which requires a cool incubator (32° C [89.6° F]), is in fish and other cold-blooded animals. Generally, only a few organisms may be isolated in some granulomas.

M. marinum is usually susceptible to rifampin, ethambutol, clarithromycin, and trimethoprim-sulfamethoxazole and intermediately susceptible to doxycycline. Treatment regimens usually include two active agents. Treatment of *M. marinum* has been successful with rifampin and ethambutol,[198,220] and one report showed good results with rifampin alone.[47] An accompanying editorial cautioned against the use of rifampin alone, however, and recommended using rifampin with ethambutol.[19] Other studies have shown success with a combination of clarithromycin and rifampin.[9] The duration of therapy, according to the literature, varies from several weeks to 18 months. Generally, response to therapy is rapid, and treatment should be continued for 4 to 6 weeks after clinical resolution.[47]

Mycobacterium ulcerans

In 1948, MacCullum[117] reported the first cases of disease caused by *Mycobacterium ulcerans*. Most cases since then have occurred in remote, tropical, or subtropical areas of the world, including parts of Africa and Australia.[116,148] In a 1-year period, 23 cases of Buruli ulcer caused by *M. ulcerans* occurred in Lambarene (Gabon).[21] Cases also have been reported in Mexico.[112] The natural reservoir for *M. ulcerans* is unknown. One report suggests the spines of a tall prickly grass known as *Echinochloa pyramidalis* as a reservoir.[180] An Australian study found evidence that mosquitoes may play a role in the transmission of *M.*

ulcerans.[106] The lesions caused by *M. ulcerans* occur mainly on the cooler superficial portions of the body. Patients harboring this organism are in otherwise good health without underlying immunodeficiency.[33] Scraping of the skin by thorns or pieces of wood has been implicated as the route of inoculation in many of the cases. The organism is fastidious, with growth requiring 6 to 12 weeks and seen only between 25° C and 33° C (77° to 91.4° F).

The incubation period for this painless infection is approximately 3 weeks. Regional lymphadenitis rarely occurs with this organism. The infection has three distinct stages, and knowledge of them can be helpful in making the diagnosis and providing treatment. The disease begins as a hard, mobile nodule. It frequently is associated with pruritus, and in Zaire is termed *mputa matadi* (the itching stone). This stage is known as the pre-ulcerative stage. In some patients, the infection resolves spontaneously, but in others it progresses to the ulcerative stage. In contrast to *M. marinum*, in which the lesions are short-lived and do not progress past the ulcerative stage, the lesions of *M. ulcerans* usually last 6 to 9 months and frequently progress and lead to deformities of limbs that may require amputation.[112] The organisms can be isolated in large numbers from the periphery of ulcers adjacent to normal tissue, which again contrasts with infection by *M. marinum*, in which few organisms are found in the lesions. The infection generally involves subcutaneous adipose tissue and leads to areas of fat necrosis, which then proceeds to overlying necrosis of the adjacent skin. The lesions can become enormous, sometimes involving a complete limb. Although numerous organisms are seen in the progressing edge of the infection, little evidence of a cellular immune response is apparent. Additionally, anergy to skin reagents prepared from *M. ulcerans* (burulin) frequently is noted at this stage.[181] The next stage, called the *reactive phase*, is then reached. Cellular infiltrates with granuloma formation occur in the lesion. The number of organisms in the lesion decreases dramatically, and a positive skin test reaction develops to the burulin. Infection with *M. ulcerans* also can cause conversion of a patient's PPD response to positive; however, conversion is seen in approximately 50 percent of cases.[33] Finally, healing may occur, but with fibrosis that often results in limb deformity.

Treatment of *M. ulcerans* infection is anecdotal at best. Treatment choices are based on the stage of infection. Lesions in the pre-ulcerative stage are best treated with excision and primary closure.[66] Successful therapy in the anergic progressive stage is considered the most difficult and involves appropriate antimycobacterial therapy for the infection. Success has been reported with isonicotinic acid hydrazide and streptomycin or diaminodiphenylsulfone and oxytetracycline combinations[33] and with sulfamethoxazole, rifampin, minocycline,[177] and clofazimine.[116] A combination of clarithromycin and rifampin has also been recommended.[67] In the final stage, healing should be promoted with as little deformity or loss of function as possible, using skin grafting and splinting and excision of fibrous tissue.[66,148] Disseminated infection in an immunocompetent child along with the development of multifocal osteomyelitis has been described.[81] (See also Chapter 98.)

Other Mycobacteria in Skin Disease

M. haemophilum has produced painful subcutaneous nodules in immunocompromised patients, particularly patients with renal transplants.[43,218] In addition, *M. haemophilum* has produced disseminated disease, including bacteremia, osteomyelitis, and pulmonary disease, in immunocompromised patients. A study of archived skin biopsy specimens using PCR for NTM identified additional NTM skin infections.[197] *M. haemophilum* was the most common organism identified. *M. chelonae* has been found to be a cause of disseminated cutaneous infection.[202] Steroid use is the predisposing factor for infection with this organism. *M. fortuitum* has been implicated in cutaneous lesions in a child involved in a motor scooter accident, with the subsequent development of lesions at the site of knee lacerations; regional adenopathy of the inguinal nodes also developed.[170] *M. fortuitum-chelonae* complex has been responsible for superficial skin abscesses in children.[14] *M. fortuitum* in adult studies also has been implicated in severe infections in immunocompromised hosts; these infections usually are rapidly disseminating, with high mortality.[217] *M. avium* has been isolated from an eyelid abscess with drainage.[164] Contaminated pedicure footbaths have been implicated in outbreaks of NTM skin infections, including a recent outbreak from *Mycobacterium bolletii* and *Mycobacterium massiliense*.[209] NTM skin infections also have occurred at insulin injection sites, acupuncture sites, and filler injection sites, with many of these caused by rapidly growing mycobacteria.[107,178] Treatment of cutaneous disease caused by these organisms is difficult at best. Four- or five-drug therapy has been tried, but with poor results.

ORGANISMS SEEN IN CHILDREN

Specific organisms and treatment guidelines are discussed in the following sections. Table 97-3 provides a quick guide to some of the more commonly used antimycobacterial agents.

Mycobacterium avium-intracellulare Complex

MAC consists of *M. avium* and *M. intracellulare*. These organisms are slow-growing, obligate aerobes that require 2 to 6 weeks for colony formation on solid media. Colonies usually are smooth but may be rough and can be transparent or opaque. These organisms grow on routine bacterial media, but growth is achieved best on selective mycobacterial media, such as Löwenstein-Jensen medium or Middlebrook 7K10 and 7K11 agar. Nucleic acid hybridization probes using target sequences of ribosomal RNA are available commercially for rapid identification of clinical isolates.[111,130] MAC infection is diagnosed most commonly by culture of blood or bone marrow.

In a study of 56 isolates from pediatric patients involving sequence analysis of the ribosomal internal transcribed spacer, Hazra and colleagues[78] showed that the closely related Mav-B and Mav-A sequevars caused most disease. Patients from geographically diverse areas of the

TABLE 97-3 **Antimycobacterial Agents***

Drug	Dosage	Form
Amikacin (A)	15-30 mg/kg/day divided three times daily	IV or IM
Azithromycin (Z)	500 mg bid (adults/adolescents); 10-12 mg/kg/day (children)	PO
Cefoxitin (X)	80-160 mg/kg/day divided four to six times daily	IV or IM
Ciprofloxacin (C)	20-30 mg/kg/day divided twice daily (adults only in United States)	PO or IV
Clarithromycin (CL)	15-30 mg/kg/day divided twice daily	PO
Clofazimine (CLO)	1-2 mg/kg/day	PO
Doxycycline (D)	2-4 mg/kg/day divided twice daily (>8 yr old)	PO, IV
Ethambutol (ETB)	15 mg/kg/day	PO
Ethionamide (ETH)	15-20 mg/kg/day divided twice daily	PO
Imipenem (IMP)	60-100 mg/kg/day divided four times daily	IV
Isoniazid (I)	5 mg/kg/day	PO
Pyrazinamide (PZA)	15-30 mg/kg/day	PO
Rifabutin (RIB)	5-10 mg/kg/day; maximum 300 mg/day	PO
Rifampin (RIF)	10-20 mg/kg/day once or divided twice daily	PO or IV
Streptomycin (S)	20-30 mg/kg/day	IM

Infections

Disseminated MAC: HIV infected: CL (or Z) + ETB (± RIB)

MAC lung disease: CL (or Z) + ETB + RIF ± S or A (severe or cavitary disease)

Mycobacterium abscessus: CL or Z + 1 or more of A, X, or IMP

Mycobacterium chelonae: CL alone (skin disease), 2 or more of the following: CL, linezolid, IMP, or tobramycin (invasive disease)

Mycobacterium fortuitum: 2 or more of the following: CL, C, A, X, IMP, or TMP-SMX

Mycobacterium kansasii: RIF + ETB + I

Mycobacterium marinum: ETB + RIF, or CL + RIF

Data from references 69, 70, 84, 108-110, 156, 196, 204, 206, 216, 221.
HIV, Human immunodeficiency virus; *MAC, M. avium* complex; *TMP-SMX,* trimethoprim-sulfamethoxazole.

United States (i.e., Boston, Miami, and Los Angeles) had isolates with closely related patterns. The finding of related strains causing disease in epidemiologically unrelated patients is most consistent with two hypotheses: a similar subset of *M. avium* strains is more virulent and more likely to cause disease in humans, and pathogenic strains are more prevalent in the environment.

M. avium was recognized in 1890 as the causative agent of disease in chickens.[218] *M. intracellulare* was designated in 1967 and at the time was difficult to distinguish routinely from *M. avium*, thus the name *M. avium-intracellulare*. Today, with the use of DNA probes, most seroagglutination types have been discerned between the two groups. *M. avium* is the most common NTM causing disease in humans, but isolates from environmental sources are more likely to be *M. intracellulare*. Both organisms can be found in birds, soil, dust, and fresh or salt water. Infections caused by MAC strains isolated from adult patients with AIDS could be identified as either serotype 4 or 8, in contrast to patients without AIDS, in whom no predominant serotype has been identified.[94,223] Nearly all isolates of MAC from patients with AIDS have been identified as *M. avium*; in patients without AIDS, the rate of *M. avium* is approximately 55 percent, and the rate of *M. intracellulare* 32 to 40 percent.[71,223]

Lung disease has been the major manifestation of MAC infection in nonimmunocompromised adults. Most investigators thought that MAC infection occurred mainly in patients with deficient immunity or underlying lung disease. Later reports seemed to indicate, however, that normal adult hosts are at risk for development of infection with MAC and that rates are increasing.[87,143] The incidence of NTM lung disease in postmenopausal women has increased over the last 20 years, especially in slender women with scoliosis or pectus excavatum.[23] Case reports involving children are lacking in detail because they usually appear within discussions of adult patients.[146]

Pediatric case reports of disseminated disease caused by MAC have appeared in the literature. Children have had ulcerative lesions of the colon[40]; mesenteric disease with abscess formation[164]; hematogenous spread to the liver, spleen, kidneys, and adrenal cortex; lesions of the epididymis[175]; bone lesions[201]; and skin lesions. Disseminated osteomyelitis rarely is caused by NTM, but if it occurs, *M. intracellulare* most commonly is isolated.[30,98] Septic arthritis also has been reported in association with osteomyelitis.[60] Immunocompromised patients with disseminated MAC infection historically require multiple-drug therapy, including a combination of azithromycin or clarithromycin and ethambutol. Rifabutin is frequently added as a third agent.[69] Some reports indicate, however, that disseminated disease in HIV-infected patients may respond to only two agents, as mentioned earlier in the discussion of AIDS. The addition of other agents may be necessary because of the high incidence of resistant

organisms. A preliminary report showed that IFN-γ might be effective when combined with conventional therapy in some patients who are refractory to standard chemotherapy alone.[83]

Bacterial peritonitis is a common occurrence in patients regularly undergoing ambulatory peritoneal dialysis for chronic renal failure. Reports of NTM causing peritonitis have been noted.[74,137,211] In cases involving NTM with foreign bodies, such as Tenckhoff catheters, the development of infected sinus tracts is frequent. Additionally, antituberculous drug regimens in these cases generally are unsuccessful. Although the mycobacteria were sensitive to the agents used, the patients continued to have sinus tract drainage without improvement, even after removal of the foreign body.

Mycobacterium scrofulaceum

M. scrofulaceum has many characteristics similar to those of *M. avium* and *M. intracellulare* and can be found in soil, water, and dairy products. This organism is associated most commonly with lymphadenitis in children 1 to 5 years old and rarely causes other manifestations in humans. Skin and bone lesions have been reported in two children chronically infected with *M. scrofulaceum* for 10 years.[51,207] Disseminated disease caused by *M. scrofulaceum* is rare, but was recently reported in a child with IFN-γ receptor 1 deficiency.[122] Few data are available on chemotherapeutic agents for treatment of infection with this organism. Based on susceptibility patterns, three or more drugs may be necessary for treatment of serious disease. Lymphadenitis can be cured with complete excision of the lymph node.

Mycobacterium kansasii

Of the photochromogens, *M. kansasii* is the one most commonly isolated in humans. It is also the second most commonly identified NTM causing disease in the United States. In contrast to *M. avium-intracellulare* and *M. scrofulaceum*, *M. kansasii* rarely is isolated in soil but has been cultured from water and milk.[26,27] Chronic pulmonary infection is the most common manifestation of this disease and is seen mainly in adults, particularly adults with AIDS. A survey from Israel of 56 adults with *M. kansasii* pulmonary infection showed that 64 percent occurred in men, 59 percent had underlying lung disease, and none was infected with HIV.[168] Pulmonary disease occurs infrequently in children. Some children have a course similar to that of adults, with underlying pulmonary disease caused by previous tuberculosis or chronic pulmonary disease.[13,126] The clinical presentation of *M. kansasii* lung disease is similar to that of *M. tuberculosis*, including cavitary infiltrates and more frequent involvement of the upper lobes, although bilateral disease pleural effusions and lymphadenopathy are less common.[169] In contrast, other children have acute symptoms of classic bacterial pneumonia with an abrupt onset of fever and sputum production and lung consolidation on physical examination and radiographs.[13,25]

In contrast to some other nontuberculous organisms, *M. kansasii* is sensitive to most of the antituberculous drugs, particularly rifampin. Most authorities recommend the use of three drugs, including rifampin, isoniazid, and ethambutol. The treatment course usually requires a minimum of 12 months of negative sputum cultures, with therapy for 24 months needed in some patients. A study of 18 patients showed that thrice-weekly clarithromycin, ethambutol, and rifampin was effective, with a mean follow-up of 46 months.[67] Patients with AIDS and *M. kansasii* infection have responded to this three-drug regimen, but the total duration of therapy is unknown at this time. In children with AIDS, the diagnosis of *M. kansasii* infection is rare, and the clinical response to therapy has been poor.[85] Cases have been reported in other immunocompromised children, including a 7-month-old boy with disseminated *M. kansasii* infection and numerous organisms found in his spleen at autopsy.[124] *M. kansasii* also has been reported to cause meningitis; the patients died despite the use of antimycobacterial therapy.[86,161] In another report, an 18-month-old previously healthy boy developed chronic septic arthritis of the ankle with adjacent osteomyelitis of the distal tibia[213] resulting in significant bone destruction.

Mycobacterium malmoense

Buchholz and coworkers[20] reviewed infections with *M. malmoense* in the United States from 1993 to 1995. Only 1 of 73 patients was younger than 10 years. This patient had cervical lymphadenitis and was cured with surgical excision alone. This organism, which frequently is overlooked on standard Löwenstein-Jensen egg medium, grows at 25°C to 37°C (77° to 98.6°F). The organism is slow-growing, and it may require 8 to 12 weeks for colonies to become visible on solid media. The BACTEC system was shown to be superior in isolating *M. malmoense* in one study of children with lymphadenitis.[82] Bone marrow involvement also was described in a patient with chronic granulocytic leukemia.[52] PCR may improve the identification of this organism. The study by Buchholz and colleagues[20] showed that prolonged combination therapy with isoniazid, rifampin, ethambutol, and pyrazinamide after surgical excision was effective in some cases.

Rapidly Growing Mycobacteria

NTM that form colonies on subculture within 7 or fewer days are referred to as *rapidly growing mycobacteria*. The *M. chelonae-abscessus* group consists of *M. chelonae*, *M. abscessus*, *M. bolletii*, *and M. massiliense*. The *M. fortuitum* complex consists of *M. fortuitum*, *M. peregrinum*, and biovariant 3.[103,222] Multilocus DNA sequencing may be needed to differentiate rapidly growing mycobacteria to the species level.[1,227] Patients typically have an underlying condition such as immune suppression or cystic fibrosis and may have a catheter or other implanted device. The most frequent manifestations of rapidly growing mycobacteria include pulmonary infections, bloodstream infections, skin and soft tissue infections, osteomyelitis, device-associated infections, and disseminated disease.[145,222]

M. abscessus, as stated earlier, is related closely to *M. chelonae* but should be designated as a separate species.[103]

Manifestations of *M. abscessus* infection usually involve pulmonary, bloodstream, cutaneous, or occasionally disseminated disease.[68,204,222] *M. abscessus* is the most common rapidly growing mycobacteria isolate causing pulmonary disease.[68] Underlying conditions such as bronchiectasis, gastroesophageal disorders with chronic vomiting, and cystic fibrosis are frequently present. Multilobar nodular bronchiectatic disease is the most common presentation. Cutaneous disease is often related to surgery or trauma and manifests as purple nodules. Maxson and associates[123] reported a case of osteomyelitis caused by *M. abscessus*.

Wallace and associates[202] provided the largest series of patients with skin, soft tissue, and bone involvement with *M. chelonae*, which is the primary clinical manifestation. Steroid use seemed to be the factor associated most commonly with the development of disease. Adult renal transplant patients also have been described with skin and subcutaneous tissue involvement caused by *M. chelonae*.[36] *M. chelonae*, likewise, has been described as an etiologic agent for otitis media, probably from contamination of ear, nose, and throat instruments with colonized water sources.[115] Cases of keratitis caused by *M. chelonae* have been reported after laser in situ keratomileusis (LASIK).[59,225] Pulmonary disease is less common.[68] With the improved ability to distinguish *M. abscessus* and *M. chelonae*, many isolates that were once identified as *M. chelonae* may now be identified as *M. abscessus*.[222]

M. fortuitum complex is one of the most frequently isolated rapidly growing mycobacteria and causes a range of diseases, including pulmonary, wound, lymphadenitis, and catheter infections.[145,222] *M. fortuitum* and *M. chelonae* have been implicated in sternal wound infections and endocarditis and have occurred in outbreak-type settings.[102,157,187] Patients responded to surgical débridement and amikacin with cefoxitin. A case series from Hong Kong reported successful treatment of *M. fortuitum* sternotomy infections with the use of a single daily dose ofloxacin as monotherapy in three patients.[226] Pulmonary disease with findings similar to those in *M. abscessus* occur in patients with *M. fortuitum*, but primarily in patients with gastroesophageal disorders with chronic vomiting.[68]

Other rapidly growing mycobacteria include *M. mucogenicum*, which is commonly isolated in cancer patients. In this population, *M. mucogenicum* is the rapidly growing mycobacteria most frequently associated with bloodstream and catheter-associated infections.[222] An outbreak of *M. mucogenicum* catheter-associated bloodstream infections occurred in eight pediatric hematology and oncology patients.[166] Six of the patients were successfully treated with catheter removal alone. *Mycobacterium neoaurum* also has been associated with catheter-associated bloodstream infections in immune-suppressed patients, including children.[205] *Mycobacterium smegmatis*, which resembles *M. fortuitum*, is a rapidly growing mycobacterium responsible for skin and soft tissue infections.[203] A case of disseminated infection has been reported in a child with inherited IFN-γ receptor deficiency.[138] *M. massiliense*, which is a rapidly growing mycobacterium closely related to *M. abscessus*, was associated with an outbreak of intramuscular injection–associated soft tissue infections in adults and children.[96] *Mycobacterium septicum* is a recently described rapidly growing mycobacterial species associated with catheter-related bacteremia.[163] *Mycobacterium wolinskyi* is an uncommon cause of posttraumatic and postsurgical wound infections and osteomyelitis.[7] As our ability to detect and distinguish different mycobacterial species improves, the number of mycobacterial species implicated in human infection will likely continue to increase.

Treatment of rapidly growing mycobacteria usually requires combination therapy involving at least two agents. Because susceptibility differs across species, these bacteria should be identified to the species level and treatment based on susceptibility testing. In general, skin and soft tissue disease should be treated for at least 4 months and bone disease for at least 6 months. Surgery may be required for extensive disease. For infections involving implants, the foreign body should be removed. Pulmonary disease often is difficult to treat, but a goal of at least 12 months of negative sputum is reasonable.[69]

OTHER SITES OF INFECTION

Carpal tunnel syndrome in adults has been reported as being caused by *M. szulgai*, an uncommon scotochromogenic mycobacterium.[184] In a review of 21 cases of *M. szulgai*, pulmonary disease was most common, with disseminated disease more common in immune-suppressed patients.[199] Effective treatment included débridement, ethambutol, and rifampin. Other infections in humans include choroiditis,[34] panniculitis,[160] parotitis,[29] genitourinary tract infection,[17,188] and synovitis.[185] Ear infections with NTM also have been reported, as has mastoiditis.[58,134,183] More recently, infection of Broviac catheters in pediatric patients with leukemia and hemodialysis and peritoneal dialysis catheters has been described.[24,28,108,166,194] In all cases, removal of the catheter was required for resolution of the infection.

With the continued proliferation of immunocompromised patients because of AIDS and new treatment modalities that induce an immunocompromised state (e.g., organ transplantation, new immunosuppressive drugs), NTM probably will continue to remain important pathogens. With newer isolation techniques and new technology such as DNA probes, the ability to diagnose these infections and understanding of the pathogenesis of the infections that these organisms produce should improve, as should the ability to treat these infections.

CHAPTER 98

Leprosy and Buruli Ulcer: The Major Cutaneous Mycobacterioses

Andrea T. Cruz

Mycobacterial infections in humans date to at least the 10th millennium BCE, with evidence of tuberculosis in Neolithic skeletons from Heidelberg, Germany,[14] Egyptian mummies,[299] and from pre-Columbian Mesoamerica.[79] Evidence of lepromatous leprosy has been found in burials in India dating back to 2000 BCE, correlating with Vedic scriptural references to leprosy.[287] Although the origins of mycobacterial infections in humans are unknown, most authorities speculate that domestication of animals in the Neolithic era promoted the transmission of mutants of *Mycobacterium tuberculosis* from livestock to humans. The origins of leprosy and Buruli ulcer and their respective etiologic agents are understood less well but may involve interplay among environmental mycobacteria, animals, and humans.[317] After tuberculosis, leprosy and Buruli ulcer are the second and third most common mycobacterial infections in humans. Leprosy and Buruli ulcer are the two most common cutaneous mycobacterioses.

Tuberculosis and other cutaneous mycobacterial infections are discussed in Chapters 96 and 97. This chapter is devoted to the two cutaneous mycobacterioses that are of greatest medical importance: leprosy and Buruli ulcer.

LEPROSY

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae* that principally affects the cooler parts of the body, especially the skin, upper respiratory tract, testes, eyes, and superficial segments of peripheral nerves. Although leprosy has affected nearly every part of the world at some time, its geographic origin is only now being unraveled.[239]

The World Health Organization (WHO) reported that in 1999, approximately 800,000 patients were being treated for active leprosy and that, also in 1999, 738,000 new patients were reported.[407] By 2010, these numbers had decreased to 192,000 and 228,000, respectively.[412] Many authorities consider that the total global prevalence of patients with active leprosy is much higher (1.5 to 2 million),[11] however, and are underreported because of the stigma associated with leprosy.[143] Several million more patients experience serious sequelae.[193]

In the Middle Ages, leprosy was common in Europe, reported in up to one quarter of skeletons in one ordinary (nonleper colony) Danish village cemetery.[26] Single nucleotide polymorphisms (SNPs) have indicated relatively low levels of genetic diversity, but phylogenetic analysis indicates that the most diverse strains are found in central Asia or eastern Africa.[239] European emigration and the West African slave trade, rather than crossing from Asia via the Bering Strait, likely introduced leprosy to the New World. The Silk Road may have then spread leprosy from Europe to China.[240] At least two foci in the United States were established in the 19th century by specific immigrations: Asians brought leprosy to the Hawaiian Islands and started an epidemic in the highly susceptible Hawaiians,[243] and Scandinavians introduced leprosy into the northern Midwest region of the United States.[203]

Patients with leprosy frequently experience severe stigmas, and, in Western cultures, this is attributable at least partially to a misunderstanding of what is called leprosy in the Old Testament.[30] The Hebrew word *tsara'ath* was rendered *lepra* when the Old Testament was translated into Greek in the 3rd and 2nd centuries BCE. In preparing the Latin Vulgate version in AD 405, Jerome used the word *lepra* directly from the Greek. In the first English translation from the Vulgate in 1384, Wycliffe translated *lepra* as *leprosy*, perhaps because leprosy, then common in Europe and Great Britain, seemed to portray an image of an unholy and loathsome human condition. In the original text, *tsara'ath* was not a specific disease but probably a group of diseases, the identities of which are obscure, and the word more generally referred to ceremonial uncleanness. More contemporary biblical editions include this description: "the priest shall examine the diseased spot on the skin of his body; and if the hair in the diseased spot has turned white and the disease appears to be deeper than the skin of his body, it is a leprous disease; when the priest has examined him he shall pronounce him unclean" (Leviticus 13 : 4).

Other cultures not influenced by Judaic laws and traditions have similar or more severe attitudes toward patients with leprosy.[143] Chinese literature indicates that in the 8th century BCE, patients with symptoms now recognized as symptoms of leprosy were stigmatized.[339] Similarly, the *Laws of Manu* (India, circa 1500 BCE) punish persons marrying into families with leprosy.[34] Although suicide was considered a sin under Hinduism, leprosy was an exception.[143] The stigma persists to the modern era. In 2009, the chairman of India's human rights commission recommended prosecuting leprosy patients if they had children.[38] Continuing efforts must be made to minimize the stigma peculiarly associated with leprosy. To help achieve this goal, the Fifth International Leprosy Congress in 1948 adopted a resolution to abandon the word *leper* for leprosy patient.[190] Some physicians prefer Hansen disease as a synonym for leprosy.

ORGANISM

M. leprae is a species in the order Actinomycetales and the family Mycobacteriaceae. This bacillus was seen first by Hansen in 1873 in Bergen, Norway, in lepromas from Norwegian patients, and this organism was the first reported bacterium causing chronic disease in humans.

M. leprae is an acid-fast bacillus 0.3 to 0.5 μm wide by 4 to 7 μm long. The acid-fastness of *M. leprae* is weaker than that of other mycobacteria. Viable *M. leprae* organisms stain solidly, but degenerating bacilli first stain irregularly, then become granular and eventually lose acid-fastness completely. The persistence of bacillary carcasses can be verified by silver staining techniques.[382] Staining quality provides a rapid method for determining the effectiveness of therapy. In vitro cultivation of *M. leprae* frequently is claimed, but not substantiated.[170,290] Because *M. leprae* still cannot be cultivated, identification depends on criteria other than those used routinely for cultivable mycobacteria. Current criteria for *M. leprae* are the following: (1) It does not grow on routine laboratory media, (2) it infects the footpads of mice in a characteristic manner,[192,329] (3) acid-fastness is extractable with pyridine,[52] (4) the organism invades nerves of the host, (5) suspensions of dead bacilli produce a characteristic pattern of reactions when injected into the skin of patients (lepromin reaction) with the various clinical forms of leprosy, (6) it produces the species-specific antigen phenolic glycolipid-1 (PGL-1),[109] and (7) it exhibits species-specific DNA sequences.[401]

Electron micrographs of *M. leprae* reveal a cell wall 15 to 20 nm thick around a cytoplasmic membrane that gives rise to mesosomes extending into the cytoplasm. Its cell walls contain arabinogalactan, mycolates, peptidoglycan, and protein.[211]

The genome of *M. leprae* is small (3.3 million base pairs) in contrast to that of *M. tuberculosis* (~4.4 million base pairs).[240] Only half the genome contains protein-encoding genes; the remainder comprises pseudogenes and noncoding elements. Gene deletion and decay have markedly limited the metabolic activities of *M. leprae* and may contribute significantly to failure to cultivate the organism and to its long generation time in the mouse footpad (14 days).[28,88] Localization of infections to the cooler parts of the body,[25] selective growth in the footpads of immunologically intact mice and in the ears of hamsters, and the high susceptibility of the armadillo (central body temperature of 32° to 35° C [89.6° to 95° F]) to disseminated infections all suggest that the optimal temperature for growth of *M. leprae* is less than 37° C (98.6° F).[217]

TRANSMISSION

The modes of transmission of *M. leprae* in nature have not been fully established. The frequency in children of a single early lesion in skin that usually is covered by clothing argues against the development of such lesions at the site of contact with *M. leprae*.[17] For many years, skin-to-skin contact between the patient and healthy subjects was considered the most important means of transmission, and this concept cannot be abandoned readily.[189] Intact skin of heavily infected patients discharges a few *M. leprae*, but ulcers in the skin may be a source of numerous bacilli. In some studies, bacillary load was the only factor associated with leprosy spread to index case contacts.[303] Skin-to-skin contact and fomites containing *M. leprae* could be sources of infection, but this mode has been minimized in recent years in favor of the nasorespiratory route.[153]

That the nasal mucosa of lepromatous patients harbors massive numbers of *M. leprae* has been known since Hansen's original discovery, and studies suggest that the respiratory passages could be an important source of infecting bacilli.[75] In one study, 80 percent of patients with multibacillary leprosy had *M. leprae* DNA in skin washings and 60 percent had nasal secretions testing positive for *M. leprae* by polymerase chain reaction (PCR). Household contacts were PCR-positive from skin and nasal secretion samples in 17 percent and 4 percent of instances, respectively.[153] *M. leprae* may bind to nasal mucosal cells by first binding fibronectin and attaching to fibronectin receptors on mucosal cells.[40] *M. leprae* organisms ejected in nose blowing remain viable under ambient conditions for 1 week,[66] and disseminated leprosy develops in immunosuppressed mice after the inhalation of aerosol that contains *M. leprae*.[283] Breast tissue and milk from lepromatous patients contain *M. leprae*, and infants may acquire infection from this source.[266]

Placental transmission of leprosy has been a subject of conjecture for some time, but evidence is growing for a significant influence of leprosy on fetal development and for intrauterine infection of the fetus. In a study of 156 pregnant leprosy patients in Ethiopia, the placentas were small and infants had lower birth-weight, higher risk for intrauterine growth restriction, and higher infant mortality rates than infants of nonlepromatous mothers.[83] Immunoglobulin A (IgA) and IgM antibodies for *M. leprae* are present in the cord blood of 30 to 50 percent of infants delivered by mothers with lepromatous leprosy.[213] Evidence is strong for synthesis of fetal antibodies to *M. leprae*. Occasionally, *M. leprae* has been shown in placentas and cord blood.[141,368] *M. leprae*–specific IgA and IgM levels increased in infants of lepromatous

mothers during the 3- to 24-month period after birth,[212] and two such infants had clinical leprosy at 9 and 17 months of age.[82]

Leprosy in young infants may be a common occurrence in areas of high endemicity.[116] In a report combining cases from the literature and observations by experienced leprologists, a total of at least 49 patients younger than 1 year of age with leprosy were identified.[32] In only half of these infants did the mother have leprosy or a history of leprosy. The youngest infant was 2.5 months old at the time of diagnosis. The fact that many of the mothers never had clinical leprosy suggests that they had an evanescent *M. leprae* bacteremia during gestation. A substantial bacteremia is a common finding in multibacillary disease[80,181] and is detectable in 15 percent of paucibacillary patients.[171]

The discoveries of a naturally acquired leprosy-like disease in recently captured wild armadillos in Louisiana,[363,391] chimpanzees,[78,120] a mangabey monkey from West Africa,[227] and a macaque from the Philippines provide reason to consider that leprosy is a zoonosis.[216,369,392] Reports of naturally acquired leprosy in armadillos range from 3 to 85 percent in the southern United States.[152,360-363] In all of these species, the histopathologic features resemble those in leprosy in humans, and the bacilli that cause the infection cannot be distinguished from *M. leprae*.[24,220,226] Leprosy has been transmitted successfully from the mangabey monkey to other mangabey, rhesus, and African green monkeys.[155,403] Some authorities suggest that insects, including *Aedes aegypti* mosquitoes, may ingest *M. leprae* during a blood meal from lepromatous patients and harbor viable bacteria.[12] The natural transmission of leprosy by insects remains unproven, however.

EPIDEMIOLOGY

The highest incidence rates of leprosy are found in Southeast Asia (including India), which accounted for 68 percent of new leprosy cases in 2010. The Americas accounted for 17 percent, followed by Africa (11%), Western Pacific nations (2.2%), and Eastern Mediterranean countries (1.7%).[412] While prevalence has fallen substantially in recent years, this decrease is partially due to decreased treatment durations.[289] Based on limited whole-population surveys in endemic areas, the total number of active patients may exceed the number reported by the WHO by a significant margin. The stigma of the disease and inefficiency in health care delivery systems contribute to this disparity in statistics.[143]

It is estimated that approximately 6500 persons in the United States have leprosy, of whom 3300 actively are receiving therapy; 150 new patients were reported in 2008.[251] This is a decline from a peak of over 360 new diagnoses annually seen in the 1980s. This surge was attributed in part to an influx of refugees from Southeast Asia.[191] Since 2000, an increased number of cases in immigrants from the Marshall Islands and Micronesia has been reported.[405] Most patients in the United States are immigrants, but a few indigenous patients regularly come from Hawaii, Louisiana, Texas, and other southeastern states.[182] No instances of secondary transmission from imported cases within the United States have been reported; immigrants with leprosy present no known public health risk to the population of the United States. The same situation probably is true for other nonendemic countries that receive many immigrants from endemic areas.

Hansen's discovery of the leprosy bacillus developed from his conviction that leprosy was a specific contagious disease, based on clinical, anatomic, and epidemiologic observations. In 1871 and 1872, he studied 69 families in western Norway in which several members had leprosy. The prevailing concept of that era was that leprosy was hereditary, but from data gathered on these families, Hansen showed that patients always had contact with another leprosy patient. Members of the same families with no such contacts were free of leprosy.[126] Hansen reasoned that the spread of leprosy depended on dissemination of this etiologic agent in a susceptible population. The leprosy epidemic in Nauru in the central Pacific area shows how rapidly leprosy can spread in a leprosy-naïve population.[121] Leprosy was introduced into this small island in 1912, and by 1924, one third of the 2500 inhabitants had leprosy.

The prevailing concept has been that an individual becomes infected only after experiencing repeated exposure. This concept now is doubted, and a single exposure may be sufficient in optimal conditions. One report describes leprosy transmission occurring after a single exposure from a patient to a surgeon who practiced in a leprosy nonendemic area.[2] Other reports describe inoculation leprosy after injury with a broken glass bangle[115] and after tattooing.[337] In any patient-contact situation, the number of viable *M. leprae* being shed by the patient and the degree of susceptibility of the contact both may vary. Long periods of association may be necessary before optimal conditions for infection exist.

Lymphocyte transformation studies show that occupational contacts of leprosy patients in Ethiopia have the highest rate of sensitization (58%) to *M. leprae*, followed closely by household contacts (47%). Noncontacts living in endemic areas have a lower rate of sensitization, but approximately 29 percent of the population still is sensitized.[117]

Geographic, ethnic, and socioeconomic factors may contribute to the spread of leprosy by affecting the number of untreated or ineffectively treated bacillary-positive patients and the opportunities for exposure. The percentage of patients who harbor large numbers of bacilli—generally, patients with lepromatous leprosy—is related to ethnic background. In some Asian populations, 50 percent or more of patients with leprosy have lepromatous leprosy; in Africans, this figure is 5 to 10 percent. One case-control study in Brazil noted that low educational level, prior history of food shortages, bathing weekly in open water bodies, and low frequency of bed linen changes were associated with leprosy transmission.[173] Another study, in Bangladesh, found that recent food shortage, rather than poverty per se, was the only socioeconomic factor associated with leprosy disease.[96] The association of nutritional depletion on leprosy has been described historically; the Nauru leprosy epidemic,

indolent from 1912 through 1920, became rampant after a devastating epidemic of influenza (30% mortality) left a debilitated population with marked dietary deficiencies. During the next 4 years, the incidence of leprosy increased from 4 to 346 patients.[121] Wartime malnutrition in Malaya[300] and China[340] was associated with increased morbidity and mortality with leprosy. Nonetheless, convincing evidence that the prevalence of leprosy is unusually high in chronically malnourished populations is lacking, in part because of the colinearity between malnutrition and other markers of socioeconomic deprivation.

Improvements in housing and other living conditions may play a role in the declining prevalence of leprosy. No other factor satisfactorily explains the virtual disappearance of leprosy from northern Europe after the Middle Ages and from Scandinavia in the 20th century, long before any effective chemotherapy was available. If the disease is predominantly airborne, the construction of dwellings that provide less confined sleeping quarters in this era could have contributed in a major way to the disappearance of leprosy in northern Europe and Scandinavia. Consistent with this concept is the inadequate housing that prevails in all geographic areas in which leprosy is common today. Another explanation for declining leprosy cases in Europe after the 15th century was that the rudimentary infection control and isolation of lepromatous patients may have had an impact.[327]

The presumed increased susceptibility of children is difficult to establish and may depend more on exposure to contagious patients and genetic predisposition than on other factors. The proportion of children among all detected patients is 20 to 30 percent.[110,259] Of 615 patients who were diagnosed in Louisiana between 1855 and 1970, 5 percent had disease onset at 0 to 9 years of age, and 19 percent were in the 10- to 19-year-old age group.[97] Lara,[184] in a study of 2000 children who lived in a leprosarium in the Philippines in an era when effective chemotherapy was unavailable, noted that leprosy developed in 470 (23%). Of these 470 patients, 254 were monitored closely, and in approximately 75 percent, the lesions healed spontaneously. Active, persistent disease developed in approximately 6 percent of children heavily exposed to leprosy. In most populations studied, only 5 to 10 percent of individuals are susceptible to leprosy. In adults, leprosy occurs more commonly in men than in women (2 : 1 to 3 : 1). In children, the sex ratio is approximately 1 : 1.

Genetic factors likely influence the susceptibility of some individuals to leprosy and the form of disease that develops.[98,102,103,331] Earlier studies found that if one twin has leprosy, the chance of leprosy developing in a monozygotic twin is 60 to 85 percent versus a 15 to 25 percent risk for dizygotic twins.[126] More recently, genome screening in Indian patients found an association with leprosy susceptibility on chromosome 10p13, near the gene for mannose receptor C, a phagocytic receptor on macrophages, and on chromosome 6, within the major histocompatibility complex (MHC).[334] Within the MHC, associations exist between leprosy and MHC class II genes in Indian patients, and with the tumor necrosis factor (TNF) gene in Brazilian patients.[328] Polymorphisms in the promoter regions of the interleukin (IL)-10 and TNF genes are associated with leprosy,[306] and the TNF promoter especially for the development of lepromatous or multibacillary leprosy.[297]

Certain human leukocyte antigens (HLA-DR) seem to be associated with specific forms of leprosy. *HLA-DR2* and *HLA-DR3* alleles are associated with tuberculoid disease, and *HLA-DQ1* is associated with lepromatous disease.[57] In Suriname, *HLA-DR3* is found frequently in mixed populations with tuberculoid leprosy and rarely in lepromatous patients; however, in Indians with tuberculoid leprosy, *HLA-DR2* predominates.[372] HLA-DR antigens may influence the presentation of antigens of *M. leprae* to T cells and may affect the immune response to leprosy.[262]

Growing genetic evidence supports interpopulation heterogeneity in leprosy susceptibility, and population-based studies have allowed for discrimination between household spread resulting from increased contact with secretions versus genetic predisposition. However, studies have varied widely in genes evaluated, suspected penetrance, and associated risk factors. One study in a former leprosy colony in Brazil estimated that penetrance for homozygous individuals ranged from 56 to 85 percent.[188] On chromosome 6, within the leprosy susceptibility locus region q25-q26,[229] further investigation revealed a significant association between leprosy and 17 markers near the Parkinson disease gene *PARK2* and the coregulated gene *PACRG* in Vietnamese and Brazilian families.[228] Having two of the alleles was associated with increased susceptibility to leprosy. In Malawi, a large case-control candidate gene study of leprosy susceptibility found that homozygotes for a silent T-to-C change in codon 352 of the vitamin D receptor gene were at higher risk, whereas homozygotes for the McCoy b blood group defining variant K1590E of the complement receptor 1 gene seemed to be protective.[103] One report from Iran showed that interferon (IFN)-γ receptor-1 gene promoter (IFNGR1) polymorphisms increased susceptibility to leprosy in a family.[377] A genomewide association study from eastern China indicated that SNPs in the nucleotide-binding oligomerization domain-containing protein 2 (NOD2)-mediated signaling pathway, which helps mediate innate immune responses, were associated with increased leprosy susceptibility.[419]

Toll-like receptors (TLRs), molecules present on the surface of innate or native immune cells, mediate cytokine production on encountering a foreign invader, including mycobacteria, and ultimately may influence the pattern of specific immunity, which is especially relevant in leprosy.[205,294] Studies in Korea found that lepromatous leprosy occurred more commonly in patients with a mutation in the TLR-2, associated with altered production of IL-10 and IL-12, underscoring the role early cytokine responses against *M. leprae* may play.[159-161] Another SNP, this one in the TLR-1 transmembrane domain, was associated with diminished nuclear factor-κB (NFκ-B) activity and found to have reduced cytokine responses to *M. leprae*.[230] Some TLR-1 mutations are protective and are more commonly seen in European populations than in Africa.[404] In African patients, polymorphisms in the *NRAMP1* gene, a gene also associated

with cellular immunity to *M. tuberculosis*, are associated with lepromatous leprosy,[210] as shown in the Mitsuda reaction.[7,279]

In Texas and Louisiana, the ratios of autochthonous to imported leprosy patients are the highest in the continental United States. Indigenous leprosy is highly prevalent in armadillos in only those two states,[25,343,390,391] but also has been reported in armadillos found in Alabama, Arkansas, Mississippi, and northern Mexico.[182,194,363,398] No cases of transmission of leprosy to humans from naturally infected mangabey monkeys or chimpanzees have been reported, but this potential exists.[120,219]

PATHOGENESIS AND PATHOLOGY

M. leprae causes disease by its ability to survive and multiply in macrophages (Fig. 98-1).[317] If macrophages of the host digest the bacilli early, disease is undetectable or the patient has only minimal lesions. If the macrophages are totally incapable of destroying the organisms, widely disseminated lepromatous leprosy follows. Survival of *M. leprae* in macrophages depends on the immune response of the patient; knowledge of immunity to *M. leprae* is necessary for understanding the mechanism of pathologic changes in leprosy.

Immunity

The immunopathogenesis of leprosy can be understood by examining the polar nature of the condition, whereby tuberculoid disease is characterized by one or several well-demarcated lesions, borderline disease manifests with a modest number of medium-sized lesions, and lepromatous disease manifests with widespread poorly demarcated lesions (Table 98-1). Each type is associated with a different immunologic profile, especially within the lesions.

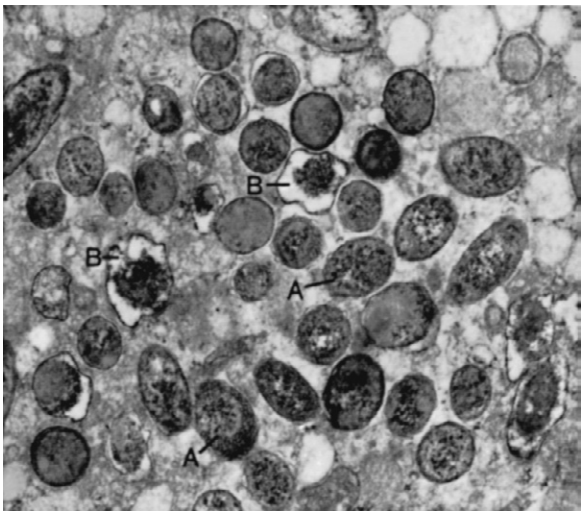

FIGURE 98-1 ■ Electron micrograph of a portion of a globus of *M. leprae* within a histiocyte in a leproma in the skin. Cross sections of well-preserved (**A**) and degenerated (**B**) bacilli are presented (×45,000). (Courtesy Dr. S. C. Chang.)

The ability of an individual to resist *M. leprae* is assessed readily by the induration provoked by an intradermal injection of a suspension of killed *M. leprae* prepared from lepromatous tissue. Lepromatous nodules of patients were the traditional source, but now infected tissue from armadillos commonly is used.[221] The reagent is known as *lepromin*, and the response is known as the *lepromin reaction*.[232] This reaction has two components: an early response at 48 hours (Fernandez reaction) and a late response at 3 to 4 weeks (Mitsuda reaction). The Mitsuda reaction is the most consistent and is used by clinicians as an aid in classifying the clinical forms of leprosy.

Mitsuda reactions are strongly positive (>5 mm in diameter) in tuberculoid patients, weak or negative (0 to 2 mm) in lepromatous patients, and intermediate (3 to 5 mm) in patients with borderline disease. The reactions are a direct measure of delayed hypersensitivity or cell-mediated immunity to *M. leprae* antigens; lepromatous patients are anergic to *M. leprae*, akin to anergy to the tuberculin skin test (TST) seen in children with tuberculous meningitis or miliary tuberculosis. Also similar to the TST, the lepromin reaction has no value in establishing the diagnosis because a high percentage of any population is Mitsuda-positive. One study evaluated the Mitsuda response in Indian children residing in leprosy-endemic regions. Percent positivity was higher in low-endemic regions than high-endemic areas (93% and 88%, respectively), indicating that the Mitsuda response is independent of *M. leprae* exposure.[324] Modifications of the lepromin reaction with the use of concentrated lepromin show that macrophages at the test site in lepromatous patients cannot clear *M. leprae* from the skin, whereas in tuberculoid patients, the bacilli are destroyed efficiently.[54]

Nonspecific factors participate in host defense against *M. leprae*. Complement promotes phagocytosis of leprosy bacilli.[311] After phagocytosis occurs, phagolysosomal fusion and intracellular killing ensue, perhaps by oxygen-independent mechanisms. Although the precise mechanisms of specific immunity remain elusive, abundant experimental evidence indicates that in a lepromatous patient, cell-mediated immunity to *M. leprae* is markedly suppressed. Delayed hypersensitivity skin test reactions to many antigens often are depressed, but they are depressed most consistently and most severely to *M. leprae*.[36] The degree of suppression is gradually less pronounced in clinical forms of disease that are progressively nearer tuberculoid leprosy.[392]

A continuous decrease occurs in the sensitivity of peripheral blood lymphocytes to *M. leprae* that proceeds from tuberculoid to lepromatous patients.[247] Many investigators consider that the defect in cell-mediated immunity to *M. leprae* is in T-lymphocyte function or in the interaction of T lymphocytes with macrophages. Total numbers of circulating T lymphocytes are decreased in lepromatous patients,[86] but no consistent alteration occurs in the percent distribution of circulating T-cell subsets, particularly in the helper-suppressor (T_H1/T_H2) cell ratio.[281]

Within tuberculoid and lepromatous lesions, immunophenotypic and functional profiles of the infiltrating T

TABLE 98-1 **Criteria for Classification of Leprosy**

Group	Clinical Features	Histologic Features	Lepromin Reaction (Mitsuda)	Bacillary Density
Tuberculoid	A single or few anesthetic macules or plaques Borders well defined Peripheral nerve involvement common	Epithelioid-lymphocyte granulomas, with or without giant cells, in skin and nerves No subepidermal clear zone Bacilli in nerves, but rare	Strongly positive	Rare
Borderline-tuberculoid	Lesions similar to those of tuberculoid, but more numerous Borders of lesions less distinct Satellite lesions sometimes present around larger lesions Peripheral nerve involvement common	Granulomas similar to those in tuberculoid Nerves are infiltrated Bacilli frequently found in nerves	Positive	Scanty
Borderline	More lesions than in borderline-tuberculoid Borders more vague Satellite lesions often seen Peripheral nerve involvement common	Epithelioid cells and histiocytic infiltrations focalized by lymphocytes Nerves show increased cellularity Bacilli readily found in nerves	Negative or weakly positive	Moderate
Borderline-lepromatous	Lesions are numerous and similar to those of borderline Some nerve damage	Histiocytic infiltrations show a tendency to evolve toward epithelioid cells and foamy cells Lymphocytes present Nerves have less cellular infiltration Bacilli plentiful in nerves	Negative	Heavy
Lepromatous	Multiple, nonanesthetic, macular or papular, symmetrically distributed lesions No neural lesions until late Late complications of madarosis, leonine facies, testicular damage	Foamy histiocytes containing large numbers of bacilli Few or no lymphocytes Subepidermal clear zone Numerous bacilli in nerves and perineurium without significant intraneural cellular infiltration	Negative	Very heavy
Indeterminate	Vaguely defined hypopigmented or erythematous macule	Often indistinguishable from mild nonspecific dermatitis Lymphocytes and histiocytes around skin appendages and nerves	Weakly positive or negative	Negative or scanty

cells differ markedly and are important factors in understanding the immunopathogenesis of leprosy.[236,237,278] In tuberculoid lesions, the CD4/CD8 T cell ratio is approximately 2:1, and the lesions are characterized by a T_H1- or T_H1-like profile, containing abundant mRNA transcripts for numerous proinflammatory cytokines that confer strong cell-mediated immunity, including IL-2, IFN-γ, and IL-12.[417] Notably, $CD4^+$ T cells in tuberculoid lesions produce IFN-γ.[304] In lepromatous lesions, the CD4/CD8 ratio is approximately 1:2, and the lesions are characterized by a T_H2- or T_H2-like profile, containing mRNA transcripts for anti-inflammatory cytokines that include IL-4 and IL-10, factors associated with weak cell-mediated immunity but strong humoral responses.[417] The $CD8^+$ T cells in lepromatous disease produce IL-4.[304] In contrast to Buruli ulcer (see later discussion of Buruli ulcer), induction of apoptosis in the lesions does not seem to play a major role in pathogenesis.[386] This immunologic dichotomy between tuberculoid and lepromatous lesions is consistent with the paradigm that robust cell-mediated immunity limits disease progression and that humoral immunity has little or no effect. In addition to genetic predisposition (see discussion of epidemiology), an important immunologic factor may relate to host innate responses, when *M. leprae* is first encountered. TLRs on innate immune cells may recognize mycobacterial lipoproteins, generating cytokines that mediate specific or adoptive responses toward a T_H1 or T_H2 direction.[29,233]

In lepromatous lesions, T_H1 and T_H2 cells are admixed among the macrophages. Suppressor activity is generated by lepromin in vitro in peripheral leukocytes from lepromatous patients but not in cells from tuberculoid patients.[209] This suppressor activity also may be induced by PGL-1 of *M. leprae*,[136,208] but it is unrelated to the type of leprosy.[273] PGL-1 abounds in the tissues of

lepromatous patients. Secondary immunosuppression in advanced lepromatous leprosy may result from blockade of thymus-dependent areas of lymph nodes by *M. leprae*–laden macrophages.[365] Specific suppressor T-cell activity in immunosuppression in leprosy remains controversial.[164]

Macrophages of lepromatous patients are thought to have the capacity to kill, digest, and clear *M. leprae* if they are activated.[133] Patients with lepromatous leprosy fail to produce IL-2, but IL-2 restores the proliferation of lymphocytes in response to specific antigens.[128] Defective IFN-γ is produced by lymphocytes from lepromatous patients on stimulation by *M. leprae* antigens.[257] IL-2–bearing lymphocytes are reduced markedly in lepromatous infiltrations in tissues.[235] Suppressor T cells may influence IL-2 production in situ and reduce the proliferation of specifically sensitized T cells to release IFN-γ, with the result that macrophages are not activated. The injection of IFN-γ or recombinant IL-2 into the skin of lepromatous patients causes a local influx of $CD4^+$ T cells along with the formation of epithelioid and giant cells and a reduction in bacillary load.[163,379] Therapy with IL-2 or IFN-γ induces the secretion of TNF-α; however, the activity of this toxic molecule may be inhibited by thalidomide or pentoxifylline.[162,357] Whether the increasing use of TNF-α antagonists would be associated with the development of leprosy from latent infections or perhaps be useful in the management of leprosy reactions remains unclear.[91,315]

Immunoglobulin production (i.e., IgG, IgA, and IgM) usually is elevated only slightly in tuberculoid patients but is elevated markedly in lepromatous patients, consistent with the predominant T_H1 versus T_H2 responses.[37] The total number of B lymphocytes is increased in the blood of lepromatous patients, as is the circulating antibody to mycobacterial antigens.[107,253]

The role of immunologic processes in damage to nerves in leprosy is poorly understood. Some observations suggest that antineural antibodies in the sera of many patients, especially patients with lepromatous disease, are related to such damage.[264] TNF-α is associated with macrophage infiltration of peripheral nerves in reversal reactions.[174] Infected Schwann cells present antigens to T cells, rendering them targets for immune attack.[317]

Histopathology

Biopsy specimens from well-defined lesions of leprosy should be taken from the active border and fixed in buffered 10 percent formalin or other suitable fixative. The Fite-Faraco staining method conventionally is used because the Ziehl-Neelsen stain does not show *M. leprae* optimally in tissue sections. However, Fite-Faraco staining is time-consuming and can result in observer fatigue, particularly in paucibacillary cases. One study showed that rhodamine-auramine fluorescent staining demonstrated organisms in 70 percent of cases, in contrast to 45 percent for Fite-Faraco staining.[254] A histopathologic diagnosis of leprosy must not be made unless the evidence is convincing. In nonendemic regions, providing additional history to the pathologist can allow for clinicopathologic correlation.[292]

FIGURE 98-2 ■ Hypopigmented macule of indeterminate leprosy on the anterior surface of the leg of an Indian girl. (See companion Expert Consult website for color version.)

Indeterminate Leprosy

In indeterminate leprosy (Fig. 98-2), the immune potential of the patient is not portrayed clearly in the cellular reaction. Only a mild chronic inflammation is found, with small infiltrations of lymphocytes or histiocytes along neurovascular channels and sometimes around appendages (Fig. 98-3). If leprosy is suspected, all nerves in the dermis and subcutaneous tissue in numerous sections of the biopsy specimen must be searched for acid-fast bacilli, even if no inflammatory changes within the nerves are present. Sometimes acid-fast bacilli appear only in the arrector pili muscles or subepidermal zone,[285] but are rarely seen in normal-appearing skin.[33] Angiogenesis is not common in indeterminate leprosy skin lesions, in contrast to other forms.[20] A histopathologic diagnosis of leprosy cannot be made unreservedly in indeterminate leprosy without showing acid-fast bacilli. Molecular biologic studies rarely are helpful in diagnosing indeterminate leprosy.

Tuberculoid Leprosy

Patients with tuberculoid leprosy (Fig. 98-4) have a high level of cell-mediated immunity to *M. leprae*, which is reflected in the cellular reaction. Granulomata composed of epithelioid cells, Langhans giant cells, and lymphocytes are present in the dermis or subcutaneous tissue (Fig. 98-5A). Frequently, upper dermal granulomata invade the lower layers of the epidermis (see Fig. 98-5A). Damage to nerves is a distinctive feature; in old, advanced lesions, all cutaneous nerves may be damaged beyond recognition (see Fig. 98-5B). Occasionally, S-100

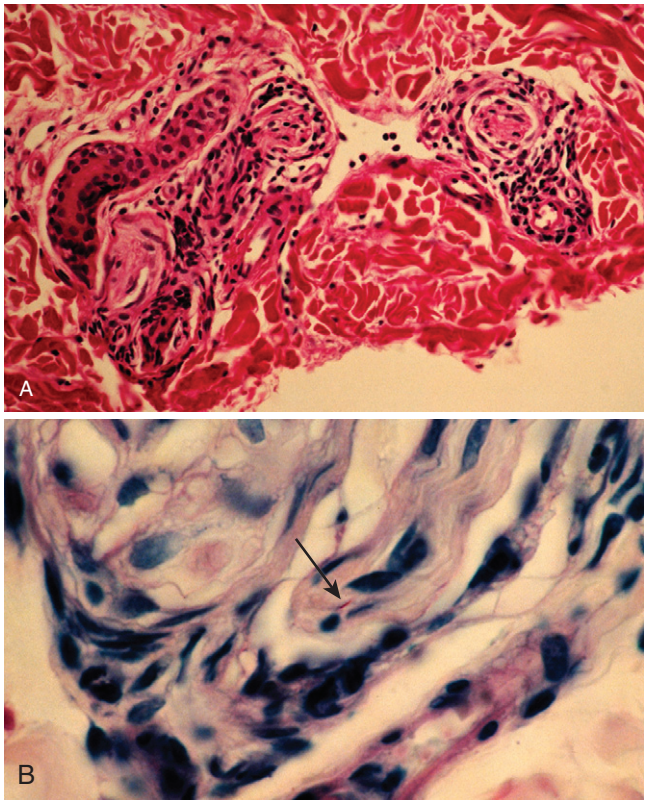

FIGURE 98-3 ■ **A,** Indeterminate leprosy showing only mild infiltrations along neurovascular channels in the deep dermis (hematoxylin and eosin stain). **B,** Only a single acid-fast bacillus was found in one deep dermal nerve (*arrow*) after a search of multiple sections (Fite-Faraco stain). (See companion Expert Consult website for color version.)

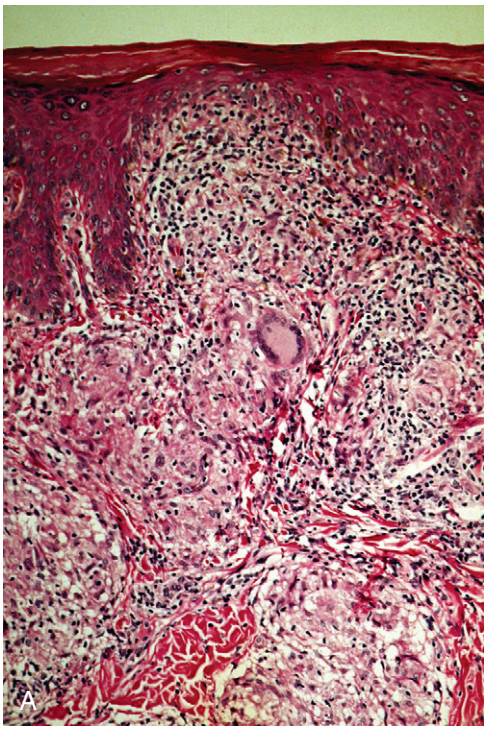
FIGURE 98-4 ■ Tuberculoid leprosy in a 12-year-old Congolese boy. This was the only lesion, and it has a well-defined papulated border with central healing. (See companion Expert Consult website for color version.)



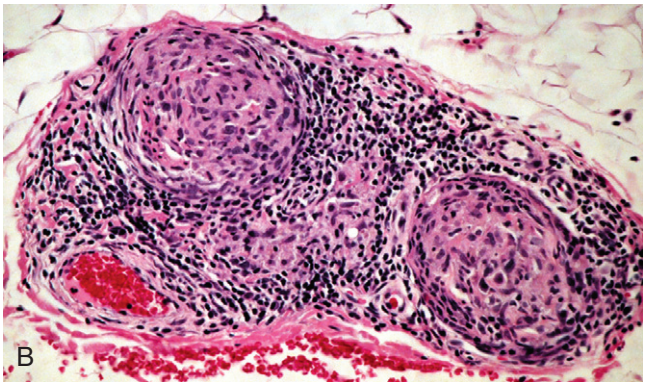


FIGURE 98-5 ■ **A,** Tuberculoid leprosy with a dense granulomatous infiltration that invades the epidermis. Granulomata contain epithelioid cells, Langhans giant cells, and lymphocytes (hematoxylin and eosin stain). **B,** High magnification of a nerve bundle in the subcutaneous tissue of section in **A.** Granulomata have nearly completely destroyed the nerves. Remnants of nerves contained rare acid-fast bacilli (hematoxylin and eosin stain). (See companion Expert Consult website for color version.)

immunostaining helps reveal a neural pattern of Schwann cells if a question exists as to whether nerves are damaged. Schwann cells are increased in number in early lesions, and the nerves are invaded by mononuclear cells. Bacilli rarely are found, and often many sections must be searched to locate a single bacillus. The bacilli usually are within remnants of dermal nerves but sometimes are located just beneath the epidermis. When major nerve trunks are involved, they contain typical tuberculoid infiltrates that eventually may replace the entire nerve. Occasionally, caseous "abscesses" are present in large nerves, but they are rare in children.

Borderline Leprosy

Borderline leprosy represents a broad spectrum of clinical (Fig. 98-6) and histopathologic variations (see Table 98-1). In the borderline-tuberculoid variety, strong cell-mediated immunity still is evident by the large numbers of epithelioid cells and lymphocytes. The nerves usually are damaged less and are identifiable more readily than

FIGURE 98-6 ■ Borderline lepromatous leprosy in a Filipino. There are many plaques, some with well-defined borders and others vaguely defined. The erythematous plaques indicate that the patient is undergoing an upgrading reversal reaction (type 1). (See companion Expert Consult website for color version.)

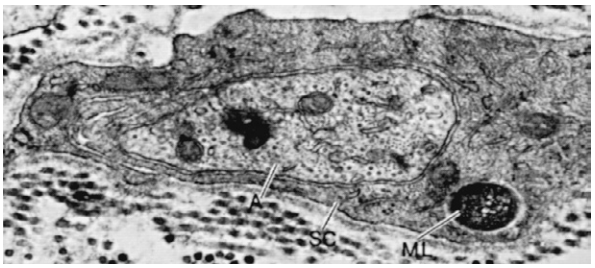

FIGURE 98-7 ■ Electron micrograph of a portion of a damaged dermal nerve in borderline leprosy. A nonmyelinated axon (*A*) is surrounded by a Schwann cell (*SC*) that contains a single *M. leprae* bacillus (*ML*) (×60,000). (Courtesy Dr. S. C. Chang.)

in tuberculoid leprosy. *M. leprae* often remain rare but are seen more readily than in tuberculoid leprosy in nerves (Fig. 98-7) or in the subdermal zone. Acid-fast bacilli can be seen in arrector pili muscle in normal-appearing skin in 17 to 25 percent of cases of borderline leprosy.[33] In the central portion of the borderline area of leprosy, the epithelioid cells are not surrounded by large numbers of lymphocytes and Langhans giant cells are uncommon. The subepidermal area is free of infiltrating cells and nerves are not damaged severely, but the perineurium often is thickened by epithelioid cells. Some histopathologists do not recognize the borderline area of leprosy as an entity because there is usually a suggestion that the lesion is on either the borderline-tuberculoid or the borderline-lepromatous side of the spectrum of the disease.[151] Borderline-lepromatous lesions reveal a low level of cell-mediated immunity. The

FIGURE 98-8 ■ Advanced lepromatous leprosy in an adolescent Filipino. Skin of most of the face, especially the alae nasi, is diffusely thickened. Eyebrows are thinned. (See companion Expert Consult website for color version.)

granulomata comprise mostly macrophages, but contain many irregularly distributed lymphocytes. A few nests of epithelioid cells may be present. The perineurium of the nerves is infiltrated with cellular exudates. Nerves are easily identified and contain many bacilli.

Lepromatous Leprosy

Prelepromatous lesions show only a mild proliferation of macrophages around vessels, nerves, and appendages. Acid-fast bacilli are few and often difficult to show. Anergy to *M. leprae* becomes apparent early in the lepromatous lesion (Fig. 98-8), with the bacilli-laden macrophage (Virchow cell or lepra cell) being the predominant inflammatory cell. In early lesions, they tend to accumulate around vessels, nerves, and appendages, but they eventually may replace the entire dermis (Fig. 98-9A). The infected macrophages are supported by a delicate stroma and supplied by a rich network of capillaries. As the macrophages age, they become vacuolated (foamy), largely from their lipid content. In developing lesions, the intracellular bacilli are arranged in small bundles (see Fig. 98-9B); in advanced lesions, dense masses of bacilli termed *globi* may replace nearly the entire cytoplasm of the macrophage. Infiltrating cells do not invade the epidermis but leave a narrow subepidermal clear zone. Many bacilli are found in the dermal nerves and frequently in endothelial cells, walls of blood vessels, arrector pili muscles, and epithelial cells of hair follicles.[245] In one case series, acid-fast bacilli were found in arrector pili muscle in normal-appearing skin in more than 50 percent of patients with lepromatous leprosy,[33] with implications for both disease extent and recurrence risk. Plasma cells vary in number and probably reflect B-lymphocyte hyperactivity.[107] Few lymphocytes are in a lepromatous lesion. Large nerve trunks may show typical lepromatous infiltrations.

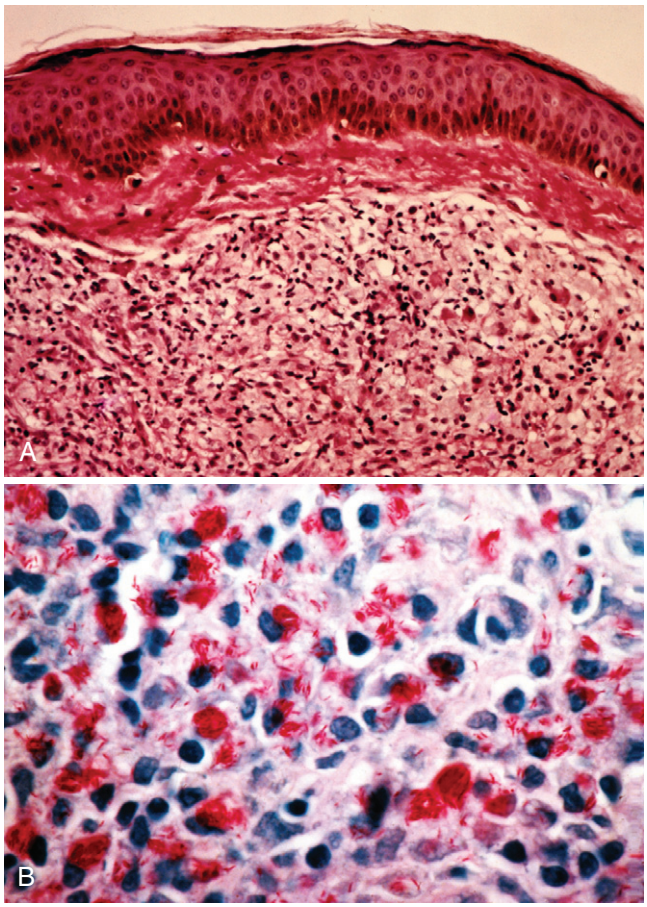

FIGURE 98-9 ■ A, Advanced lepromatous leprosy showing replacement of dermis by foamy histiocytes and very few lymphocytes. Note thin subepidermal clear zone (hematoxylin and eosin stain). **B,** Higher magnification of same biopsy specimen showing clumps of *M. leprae* (globi) in histiocytes in a leproma in the skin (Fite-Faraco stain). (See companion Expert Consult website for color version.)

Occasionally, in patients with lepromatous leprosy, elevated firm nodules form in the skin, especially in relapsing disease. Because of the characteristic histologic pattern of these lesions, in which the spindle-shaped histiocytes resemble fibrocytes, this form is called *histoid leprosy.*[318,383] Lepromatous leprosy is disseminated widely, and lepromatous infiltrations frequently are found in the upper respiratory tract, as far down as the larynx, and in the eyes and testes. In adults, the testes sometimes are densely infiltrated, with subsequent development of sterility and gynecomastia, but these complications are rare findings in children. Lymph nodes often are infiltrated by bacilli-laden macrophages, especially in the medulla and paracortical areas.

CLINICAL MANIFESTATIONS

The incubation period varies (usually 2 to 5 years), and no prodromal manifestations are well established. Some experienced clinicians working in areas of high prevalence recognize early signs of nerve involvement (i.e., localized paresthesia, itching, or numbness) before any visible lesions develop. Paucibacillary leprosy is defined as having one to five skin lesions, and includes all smear-negative cases. Multibacillary leprosy includes more than five skin lesions and includes all smear-positive cases. The polar forms of leprosy include tuberculoid (paucibacillary disease) and lepromatous (multibacillary) leprosy, with other forms falling between these extremes. Differentiation of paucibacillary from multibacillary disease is important for selection of the number of empirical medications started, duration of therapy, and risk for relapse and sequelae.[412]

After the incubation period, various lesions appear. The nature of the lesions depends on the immune response of the patient to *M. leprae*. So far, no strain variations of the bacillus except in drug sensitivity have been detected.[399,400] Most clinicians today follow the classification scheme outlined by Ridley and Jopling (see Table 98-1).[286] Classification is important because it aids in establishing the prognosis and treatment program for the patient. The distribution of leprosy types varies geographically. One study from the National Leprosy Control Program in Mexico reviewed more than 6000 skin biopsies obtained between 1978 and 2002. Lepromatous leprosy was the most common form, seen in 60 percent of cases; twice as many cases were multibacillary as paucibacillary.[375] In contrast, trends over 50 years in one region of India showed that in recent decades, borderline leprosy was more common and multibacillary rates had declined.[258]

Virtually all patients with leprosy have peripheral neuropathy if cutaneous sensory changes are included, and approximately 25 percent have significant deformity. In experimental studies, the pathogenesis of peripheral neuritis in leprosy involves bacillation of the endothelial cells of epineural and perineural blood vessels and lymphatics.[314,316,317] Surface proteins of *M. leprae* may bind the bacillus to Schwann cells via laminin.[276,332]

Ocular complications in leprosy are well known, especially in lepromatous leprosy. These lesions can include corneal scarring; conjunctivitis; and eyelash abnormalities, including ectropion (eversion of lid margin from globe), lagophthalmos (inability to close eyelids completely), madarosis (loss of eyelashes), and trichiasis (eyelashes growing back toward globe).[58,63,64,87,131] All patients with leprosy should be evaluated by an ophthalmologist at diagnosis and periodically thereafter, especially during any reactional episodes. Reactional episodes can involve ocular hypotension, punctate keratitis, and uveitis.[65]

Indeterminate Leprosy

An indeterminate lesion is the first manifestation of leprosy in most patients and may heal spontaneously, remain unchanged for months or years, or gradually progress toward tuberculoid or lepromatous disease. Patients with indeterminate leprosy have a single or a few macules in the skin (see Fig. 98-2). The macule is defined poorly and is mildly hypopigmented in deeper pigmented skin and slightly erythematous in lighter skin. Skin texture, sensation, and sweating within early macules are normal or only slightly altered. Peripheral nerves are

normal, and skin smears from lesions rarely contain bacilli. The definitive diagnosis can be made only by finding acid-fast bacilli in histopathologic sections.

Tuberculoid Leprosy

Tuberculoid leprosy is the paucibacillary extreme of leprosy. Patients with tuberculoid leprosy have a single or several asymmetrically distributed hypopigmented skin lesions (see Fig. 98-4). Tuberculoid lesions arise de novo or evolve from indeterminate macules. The lesion may be macular or infiltrated, but the borders always are sharply demarcated from the surrounding normal skin and frequently are finely papulated. Lesions range in size from less than 1 cm to large enough to cover entire regions, such as the thigh or buttock. Many tuberculoid lesions heal spontaneously. In large, active lesions, the centers often are healed and repigmented, although somewhat atrophic. The lesions often are hairless, hypohidrotic, and anesthetic. On the face, because of its rich innervation, the detection of hypoesthesia in early lesions requires discriminating tests. Conversely, clinicians may mistakenly diagnose leprosy in areas of the body that normally are hypoesthetic (e.g., over the elbows or knees). Despite hypoesthesia, deep pain on percussion of lesions over bone in tuberculoid leprosy, termed the *tap sign*, has been described, with a sensitivity of 67 percent and specificity of 100 percent.[179]

Involvement of peripheral nerves commonly occurs in tuberculoid leprosy (Fig. 98-10), and cutaneous nerves often can be palpated adjacent to or within lesions. The regional nerve trunks most commonly enlarged are the ulnar from the olecranon groove to midarm, lateral popliteal just distal to the head of the fibula, and posterior tibial in the medial aspect of the ankle. Enlarged or tender nerves anywhere should alert the clinician to the possibility of leprosy. Any readily palpable cutaneous nerve probably is enlarged, but evaluating the size of nerve trunks requires experience because of the wide range in normal size.

FIGURE 98-10 ■ Enlargement of the great auricular nerve in an adolescent Congolese boy. A large macule of tuberculoid leprosy over the angle of the mandible is now nearly inactive and barely visible. (See companion Expert Consult website for color version.)

Borderline Leprosy

Borderline leprosy, sometimes called *dimorphous* or *intermediate leprosy*, has features of the lepromatous and tuberculoid forms and represents a continuous spectrum of disease ranging from near-tuberculoid to near-lepromatous. It is an unstable form of leprosy and may evolve gradually toward tuberculous leprosy by undergoing reversal reactions or be downgraded toward lepromatous leprosy. Table 98-1 describes the three major subgroups of borderline leprosy: borderline-tuberculoid, borderline, and borderline-lepromatous.

In borderline-tuberculoid leprosy, the number of lesions usually is greater than in tuberculoid leprosy, and the borders of each lesion, macule, or plaque are defined less sharply than in tuberculoid leprosy. Small satellite lesions may develop around larger macules or plaques. Borderline-lepromatous leprosy often manifests with widespread nodular infiltrations or plaques of varying size (see Fig. 98-6).

Damage to nerves and the resulting deformity develop early and often are widespread. Neuropathic pain or neurotropic changes (e.g., sensory changes that lead to damaged hands or feet or a muscular weakness such as footdrop) frequently bring the patient to the physician. Severe damage to nerves occurs infrequently in young children, but can be disastrous. Prevention of this complication is an important goal of leprosy detection programs and of treatment in every patient with leprosy.

Lepromatous Leprosy

In contrast to tuberculoid leprosy, lepromatous leprosy is the classic multibacillary disease extreme. Here, the bacilli multiply freely, peripheral blood smears can be positive for acid-fast bacilli (up to 80% in one study),[80] and the disease disseminates widely, often before striking cutaneous manifestations develop. Lepromatous leprosy may evolve from an indeterminate or borderline area leprosy or may be the first recognizable form. In its earliest form, lepromatous leprosy manifests as "juvenile leprosy," a clinical entity delineated from observations of large numbers of children in homes for children of patients with leprosy in India.[244] This form, also called *prelepromatous leprosy*, is difficult to detect and frequently goes unrecognized until a more advanced stage develops. Skin texture may be altered slightly, but the vague macules with indistinct borders are detected only under appropriate lighting, preferably daylight. No changes in sensation or sweating occur in the macules, and frequently acid-fast bacilli are not detectable in skin smears. Histopathologic sections may reveal a few bacilli to confirm the diagnosis; however, if leprosy is suspected, the patient should be monitored until an explanation for the mild skin changes is found. If leprosy is present and not detected and treated, advanced forms of lepromatous leprosy develop in many of these patients (Fig. 98-11).

FIGURE 98-11 ■ Progression of lepromatous leprosy in a Hawaiian boy. The photograph on the *left* was taken in 1931, when the patient was 13 years old, and the photograph on the *right* was taken 2 years later. No effective chemotherapy was available in that era.

The hypopigmented or slightly erythematous macules of early lepromatous leprosy, similar to those of juvenile leprosy, are missed easily because they are vague and have slight, if any, sensory changes. These macules usually are small but gradually may coalesce and cover large areas of skin, even nearly the entire body. Clinical diagnosis often is missed, and over the course of a few years, advanced lepromatous leprosy develops. If skin smears or biopsy specimens are taken in the macular stage, diagnosis is virtually ensured. If the disease is not diagnosed and treated in the macular stage, infiltration of the skin increases gradually and nodules may develop. The skin is infiltrated most heavily in the cooler portions of the body, notably the ears (pinnae) and face. By this time, nerves usually are enlarged, with early signs of sensory loss in the hands and feet. Eyebrows are thinned and eventually lost, beginning at the lateral edges. These advanced changes of lepromatous leprosy are not common findings in young children but are well known.

Histoid leprosy, one variant of multibacillary leprosy, often is classified with lepromatous leprosy. Here, firm, dome-shaped nodular or papular lesions show constriction around the base. They are more commonly found in the axial skeleton.[318]

Patients of Latin American ancestry, especially patients from Mexico and Costa Rica, may contract the highly anergic diffuse form of lepromatous leprosy called *Lucio leprosy*. The disease may be so diffuse that it is not recognized until sensory changes appear in the hands and feet, and the eyebrows and other body hair begin to disappear. In advanced forms of Lucio leprosy, a marked obstructive vasculitis in the skin is present, with the production of dermal infarcts and irregular ulcers (Lucio phenomenon).[185,280] Lucio leprosy has been reported in children 7 years old.[310]

Neuritic Leprosy

Neurotic leprosy, a relatively rare form of the disease, manifests as motor or sensory impairment in one or multiple nerves in the absence of cutaneous changes. Symptoms include anesthesia, paresis, and wasting of muscles in the affected area. Nerve trunks frequently are painful, enlarged, and tender. Leprosy must be suspected in patients with any peripheral neuritis that has these features. Chronic neuropathy and nerve enlargement often persist for years after the patient has completed chemotherapy for leprosy.[130] Large leprotic nerve abscesses are rare occurrences but are exquisitely painful and may require surgical intervention for drainage.[321] Most clinicians prefer to treat such lesions with corticosteroids.

Leprosy and Acquired Immunodeficiency Syndrome

Given the history of acquired immunodeficiency syndrome (AIDS) altering the epidemiology and undermining control efforts for the other mycobacterial species with human-to-human transmission, *M. tuberculosis*, concern exists that a similar phenomenon might be seen with *M. leprae*.[367] In one study in Zambia, antibodies to human immunodeficiency virus (HIV) were found in 33 percent of patients with newly diagnosed leprosy versus 7 percent of controls.[206] Perhaps the positivity of some of these patients with leprosy can be explained by cross-reactivity between antibodies to HIV-1 and the lipoarabinomannan of *M. leprae*.[168] In other populations in Africa, HIV infection constituted an overall risk factor of 2.2 for leprosy, with 4 to 23 percent of multibacillary leprosy cases attributable to HIV coinfection.[27]

However, most studies have shown that HIV seroprevalence among leprosy patients is no higher than the general population and that clinical manifestations are similar in coinfected patients and patients with leprosy alone.* Other prospective studies show that HIV infection may not be a risk factor for acquisition of leprosy in some populations.[172,320] These observations are supported by a study of the parameters of cell-mediated immunity in coinfected patients in Brazil.[305] In these patients with borderline leprosy, the quality of the granulomata in the infiltrations of leprosy was not altered significantly despite low $CD4^+$ T-cell counts. The incidence of reversal reactions (type 1, described later) and neuritis is increased in multibacillary patients coinfected with HIV.[39] These reactions, similar to immune reconstitution inflammatory syndrome (IRIS) have been described for both forms of IRIS.[367] Paradoxical IRIS, in which worsening of leprosy lesions is seen while on both appropriate leprosy and antiretroviral therapy, has been described with borderline leprosy; reactions often are local, not systemic.[15] Unmasking IRIS, in which leprosy symptoms develop anew in a person on antiretroviral therapy, has been described in a patient with borderline tuberculoid leprosy.[187]

REACTIONS

The course of leprosy, treated or nontreated, often is interrupted by acute episodes known as reactions, which fall into two general categories: reversal reactions (or type 1) and erythema nodosum leprosum (or type 2).[74]

*References 147, 172, 180, 241, 320, 367.

Reversal Reactions

Reversal reactions complicate borderline leprosy and represent delayed hypersensitivity reactions, with an upgrading of cell-mediated immunity toward tuberculoid leprosy. Lesions become erythematous and edematous, and neuritis is a common manifestation (Fig. 98-12). Risk factors for reversal reactions include being lepromin-positive and having PGL-1 IgM antibodies.[288] Proliferation of sensitized T lymphocytes initiates reversal reactions and amplifies the inflammatory response by releasing lymphokines and activating macrophages.[293] Effective chemotherapy for paucibacillary and multibacillary patients may activate cell-mediated immunity and provoke clinical or subclinical reversal reactions. Expression of HLA-DR is increased, which may enhance production of IFN-γ by lymphocytes in granulomata.[61] Histopathologically, edema is accompanied by increased lymphocytes, epithelioid cells, and giant cells. In severe reactions, necrosis may occur, almost always in nerves. Increased levels of TNF-α may partially explain this necrosis.[22] Cyclooxygenase-2 levels are elevated in nerves and blood vessels during reversal reactions, a finding that explains why nonsteroidal anti-inflammatory drugs, including selective cyclooxygenase-2 inhibitors, often improve the condition.[267] Patients experiencing such reactions must be observed closely so that sensory loss and deformities are minimized.

FIGURE 98-12 ■ Reversal reaction (type 1) in an 8-year-old Congolese boy with borderline-tuberculoid leprosy. The left side of his face is swollen and displays mild palsy from facial nerve damage. The patient responded rapidly to oral steroid therapy. (See companion Expert Consult website for color version.)

Differentiating reversal reactions from relapsing lesions frequently is difficult and requires careful correlation of clinical and histopathologic findings. This correlation is becoming increasingly important in endemic areas, where shorter term chemotherapeutic regimens of fixed duration are used.[104,215] The following criteria for differentiating relapses and reversal reactions are suggested: a relapse involves an increased number of lesions, positive skin smears for acid-fast bacilli (for patients with a borderline area of leprosy and borderline-lepromatous leprosy), tissue reaction inconsistent with a reversal reaction, and a favorable response to chemotherapy; a reversal reaction involves an exacerbation of existing lesions, skin smears negative for acid-fast bacilli, tissue reaction consistent with a reversal reaction, and a rapid response to anti-inflammatory drugs.

Erythema Nodosum Leprosum

Formerly, erythema nodosum leprosum developed in approximately 50 percent of lepromatous leprosy patients after they had undergone a few months of chemotherapy; however, with the addition of clofazimine to the standard therapeutic regimen, the frequency is much reduced.[93] Tender erythematous subcutaneous nodules develop rapidly (Fig. 98-13); the nodules often are accompanied by fever, synovitis, and iridocyclitis.[269] Erythema nodosum leprosum resembles the Arthus reaction and is thought to result from immune complex formation.[111] Erythema nodosum leprosum is associated with serum TNF-α elevation[22,309] and intralesional increases in helper T lymphocytes.[234]

In the nodule, neutrophils and sometimes an intense vasculitis are present. Ulceration of the skin frequently accompanies severe erythema nodosum leprosum. Glomerulonephritis sometimes complicates this condition; secondary amyloidosis is a late sequela of repeated reactions and may be a consequence of the neutrophilic leukocytosis.[202] Although neutrophilic infiltration is considered by many physicians to be the hallmark of the tissue reaction, tissue from a rare patient with clinically typical erythema nodosum leprosum may not show neutrophils. In such patients, demonstration of serum amyloid A and C-reactive protein may aid in establishing

FIGURE 98-13 ■ Erythema nodosum leprosum in a Filipino adolescent girl with lepromatous leprosy. (See companion Expert Consult website for color version.)

the diagnosis.[137] Occasional patients may have mixed reversal (upgrading) reactions and erythema nodosum leprosum. These patients usually have leprosy in the borderline-lepromatous area of the spectrum.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The cardinal signs of leprosy are hypoesthetic lesions of the skin, enlarged peripheral nerve or nerves, and acid-fast bacilli in skin smears. In the absence of another clear explanation, any one of these signs strongly suggests leprosy.

An experienced observer can establish a clinical diagnosis in most patients, except those with early leprosy, with a high degree of accuracy. Because leprosy is considered one of the "great imitators,"[388] however, histopathologic evaluation is strongly recommended to supplement and confirm the clinical diagnosis. Patients with leprosy may be found in almost any geographic area, an awareness of which would minimize missed and delayed diagnoses, especially in areas of low prevalence. In the United States, the usual delay in establishing the diagnosis after the patient's first visit to a physician for symptoms related to leprosy is approximately 1.5 to 2 years. This delay often significantly worsens the prognosis.

History is important. Contact with patients with leprosy or residence in an endemic area raises suspicion of leprosy in a patient with a chronic lesion of the skin. Sensory loss or unexplained damage to hands or feet suggests damage to nerve trunks. Sometimes, a footdrop or clawhand brings the patient to a physician. Occasionally, patients with lepromatous leprosy consult an otolaryngologist first because of a chronic stuffy nose.

Clinicians must evaluate sensory changes in a lesion using the precautions already mentioned. The modalities usually tested are light touch with the use of a few fibers of cotton or calibrated nylon threads and heat and cold discrimination with the use of warm and cold water in test tubes. Much patience and repeated testing often are necessary in evaluating young children. Spontaneous sweating can be observed directly, or induced sweating can be evaluated. Hair may be completely preserved in early lesions but lost in advanced lesions. The main nerve trunks must be palpated for tenderness and enlargement. Skin in the area of discrete lesions also must be palpated gently to detect enlargement of cutaneous nerves. In the world population, leprosy is the most common cause of peripheral neuropathy and must be considered in any patient with peripheral neuropathy.[301]

Obtaining and examining smears for acid-fast bacilli is an important diagnostic procedure and should be controlled carefully by experienced laboratories. Briefly, smears are made from the edge of discrete macules or plaques, nodules, ear lobes, and nasal mucosa. Fine needle aspirate has a sensitivity over 90 percent.[207] Skin smears are made by squeezing and holding a fold of skin between the thumb and forefinger to avoid getting blood in the smear and by making a short, shallow slit in the skin with a razor blade or scalpel. The instrument is turned at a right angle to the slit, and the edges of the incision are scraped. The cells and fluid thus obtained are spread on a slide, heat-fixed, and stained by the Ziehl-Neelsen method.[378] Evaluation of smears should not be done by researchers unfamiliar with their interpretation. An occasional acid-fast bacillus may be a harmless contaminant in the staining reagents. DNA probes specific for *M. leprae* are available and are useful in identifying leprosy bacilli in tissue or nasal secretions.[75,401]

The lepromin reaction is useless for the diagnosis of leprosy.[35] Currently available skin tests with soluble *M. leprae* antigens are unreliable.[125] Enzyme-linked immunosorbent assays and gelatin particle agglutination tests for antibodies to the PGL-1 of *M. leprae* are available.[45,119,142] Although specificity for *M. leprae* is high, these tests detect antibodies to PGL-1 in only 50 percent of patients with paucibacillary leprosy. Other serologic tests for antibodies to *M. leprae*–specific epitopes on protein moieties of the bacillus are being evaluated.[265] PGL-1 antigen is detectable in the serum and urine of most multibacillary patients.[260,418] PGL-1 antibodies also have been used for early leprosy diagnosis in household contacts.[16]

Reliance on DNA probes and PCR technology may prove useful in establishing the diagnosis of leprosy in tissue sections, skin smears, and nasal smears.[75,356,399,401] Because these methods can detect a single leprosy bacillus, interpreting results, particularly in highly endemic areas, is difficult. Careful clinicopathologic correlation is essential when basing a diagnosis on DNA findings.[370] Multiplex PCR has also been piloted to detect early cases of leprosy in community-based contact tracing, and was more sensitive than acid-fast bacillus smear examination.[13] One pediatric study showed that whereas slit-skin acid-fast bacillus smears were positive in only 20 percent of cases, PCR was positive in almost 90 percent of children with borderline and lepromatous leprosy and 72 percent of leprosy cases overall.[158] Specimens for PCR amplification should be preserved in 70 percent ethyl alcohol.[44,99,122]

Historically, mouse footpad (MFP) assays have been used to screen for *M. leprae* drug resistance; however, the MFP assay is time-consuming (often requiring more than 6 months before result availability). Molecular targets for drug resistance have been identified. Resistance to rifampin (similar to *M. tuberculosis*) is associated with the *rpoB* gene, fluoroquinolone resistance with the *gyrA* gene, and dapsone resistance is associated with the *folP1* gene.[250] In one study, sensitivity was higher for PCR than for MFP.[319]

The differential diagnosis of leprosy in children is an extensive subject and can be discussed only briefly here. Superficial mycoses and postinflammatory changes commonly are confused with early leprosy. Changes in pigmentation may be caused by scars, birthmarks, and actinic dermatitis. In areas where dermal filariasis is endemic, vague macules in a black-skinned patient may appear identical to the early macules of leprosy.[31,204,218] Among the many infiltrated lesions of the skin that can resemble leprosy are leishmaniasis, lymphoma, granuloma annulare, granuloma multiforme (Mkar disease), lupus erythematosus, psoriasis, pityriasis rosea, sarcoidosis, and

neurofibromatosis. Histoid leprosy especially mimics other diseases—von Recklinghausen lesions, molluscum, erythema nodosum, subcutaneous rheumatoid nodules, and nodular syphilis.[318] Peripheral neuropathies that may simulate leprosy are those seen in Morvan syndrome, syringomyelia, lead intoxication, diabetes mellitus, primary amyloidosis of nerves, and familial hypertrophic neuropathy. Pure neuritic leprosy is in the differential diagnosis of hypertrophic neuropathies, such as those caused by amyloidosis and chronic relapsing polyneuritis, and progressive hypertrophic interstitial lepromatous leprosy frequently gives false-positive reactions for syphilis.

PROGNOSIS

Without chemotherapy, the prognosis in all patients except those with limited and self-healing disease potentially is poor. Patients with borderline or advanced tuberculoid leprosy frequently become mutilated because of neuropathy. Borderline patients can decline toward lepromatous leprosy. In patients with lepromatous leprosy, the disease is progressive and can cause death from laryngeal obstruction. Secondary amyloidosis is a frequent late sequela. Blindness may result from repeated episodes of iridocyclitis or ocular desiccation and/or keratitis from eyelash anomalies. Nerve damage as identified by electrophysiologic tests may be more widespread than realized on clinical examination. In one series of adults with multibacillary leprosy, before treatment, 92 percent of patients had abnormal nerve conduction studies, with sensory nerves being more involved than motor nerves (52% vs. 37%), and almost two thirds of patients had involvement of five or more sensory or motor nerves or both.[41] General debility and deformity eventually prevent gainful employment in many patients. Additionally, the stigma associated with the disease may have pervasive effects on the lives of affected children and adults.

If therapy is started early, the prognosis usually is excellent, and deformity and mutilation are prevented. Even after receiving successful chemotherapy, however, some patients continue to experience significant neuritis and loss of peripheral nerve function. Sometimes this "silent neuropathy" goes unnoticed by the patient and the physician.[67,395] Appropriate early attention to anesthetic hands and feet and restoration of function by reconstructive surgery can prevent most mutilation.

The lepromin test is a valuable prognostic tool because it measures the cell-mediated immunity potential of the host to acquisition of infection by *M. leprae*.[150] Patients with early macular lesions who are lepromin-negative have a poorer prognosis than patients who are lepromin-positive if treatment cannot be administered. Histopathologic evaluation made before instituting chemotherapy is important for determining the prognosis and, if available, should not be neglected.

TREATMENT

When a diagnosis of leprosy is established, chemotherapy must be initiated and appropriate measures must be instituted for preventing or correcting deformity in patients with neurotropic changes.[47,105,183] The three chemotherapeutic agents most commonly used are dapsone, clofazimine, and rifampin.[242] Although the WHO recommends only clinical findings for assessment of the therapeutic response in field programs, clinicians may wish to use additional evaluations. The effectiveness of chemotherapy is assessed readily in patients with lepromatous or near-lepromatous leprosy by the staining quality of *M. leprae* in skin smears. The response to chemotherapy in patients with tuberculoid leprosy and most borderline patients is determined by the clinical response and by histopathologic evaluation. Viability of *M. leprae* in tissues is assessed in unusual cases in the mouse footpad.

Combined chemotherapy is being accepted increasingly for all forms of active leprosy. Although experimental data are limited,[330] multidrug therapy has replaced monotherapy (Table 98-2).[76] Monotherapy with any chemotherapeutic agent is not advised for concern for selection of resistant isolates. As previously discussed, conventional methodologies for leprosy drug susceptibility are cumbersome, leading to increased emphasis on detection of resistance using molecular modalities. This has also resulted in increased surveillance capabilities. During 2010, sentinel surveillance data from nine nations (i.e., Brazil, China, Colombia, India, Myanmar, Pakistan, the Philippines, Vietnam, and Yemen) evaluated drug resistance in patients with relapsed multibacillary leprosy. Of 88 samples tested for drug resistance, 9 were dapsone-resistant, 1 was rifampin-resistant, and none were fluoroquinolone-resistant. No isolate was found to be multidrug-resistant.[413]

Dapsone

Dapsone, a bacteriostatic sulfone antimetabolite for *M. leprae*, was the first chemotherapeutic agent found to be effective; it was first used in 1941 in Carville, Louisiana.[92] The drug usually is given orally at 1 to 2 mg/kg/day as a single daily dose. The adult dose is 100 mg daily, and in the United States, dapsone is available as 25- and 100-mg tablets. The WHO guidelines recommend dapsone as part of multidrug therapy for all forms of leprosy.[411] The effect of dapsone on the bacilli is slow; 3 to 6 months of treatment is necessary to render bacilli from patients with lepromatous leprosy noninfectious for the mouse footpad. Sulfone-resistant strains of *M. leprae* are being detected with increasing frequency[395,396,413]; monotherapy with dapsone is not recommended. Dapsone usually is well tolerated but may provoke one or more of the following signs or symptoms: fever, exfoliative dermatitis, generalized lymphadenopathy, hepatosplenomegaly, or psychosis. Laboratory findings may include leukocytosis, hemolytic anemia, eosinophilia, or elevated bilirubin and serum transaminases.[5] Consideration should be given to screening children for glucose-6-phosphate dehydrogenase (G6PD) deficiency before initiation of therapy.

Rifampin

Rifampin is a bactericidal antibiotic inhibiting bacterial DNA-dependent RNA polymerase. A single large dose

TABLE 98-2 **Suggested Dosing Regimens for Leprosy from the World Health Organization[410,411] and National Hansen's Disease Program[252,*]**

Leprosy Classification	Drug	Dose†			Duration
		Age <10 Yr	Age 10-14 Yr	Age ≥ 15 Yr	
Paucibacillary[1]	Dapsone	1-2 mg/kg/day	1-2 mg/kg/day	100 mg daily	WHO: 6 months NHDP: 12 months
	Rifampin	10-20 mg/kg/day	10-20 mg/kg/day	600 mg daily (NHDP) 600 mg monthly (WHO)	
Multibacillary[2]	Dapsone	1-2 mg/kg/day	1-2 mg/kg/day	100 mg daily	WHO: 12 months NHDP: 24 months
	Rifampin	10 mg/kg/day	10 mg/kg/day	600 mg monthly (WHO) 600 mg daily (NHDP)	
	Clofazimine[3]	50 mg biweekly + 100 mg monthly (WHO) 1 mg/kg/day (NHDP)	50 mg every other day + 150 mg monthly (WHO) 1 mg/kg/day (NHDP)	50 mg daily (NHDP, WHO) ± 300 mg load monthly (WHO)	
	Minocycline (second line for dapsone or clofazimine)	25 mg monthly if <15 kg; 50 mg monthly if 15-30 kg (WHO) ND (NHDP)	50 mg monthly (WHO) ND (NHDP)	100 mg monthly (WHO) 100 mg daily (NHDP)	Extend multidrug therapy to 2 years[380]
	Ethionamide (second line for clofazimine)	50-75 mg daily if <15 kg, 150-175 mg daily if 15-30 kg (WHO) ND (NHDP)	275-375 mg daily (WHO) ND (NHDP)	275-375 mg daily	
	Ofloxacin (second line for clofazimine or rifampin)	100 mg monthly if <15 kg, 200 mg monthly if 15-30 kg (WHO) Not recommended (NHDP)	200 mg monthly (WHO) Not recommended (NHDP)	400 mg monthly (WHO) 400 mg daily (NHDP)	

[1]Tuberculoid leprosy, borderline-tuberculoid, and indeterminate.
[2]Lepromatous, borderline, and borderline-lepromatous.
[3]Higher doses may be used for patients with erythema nodosum leprosum.
*Second-line medications are italicized.
†Pediatric dosing should never exceed adult maximum. Approximate pediatric dosing,[156] as a percentage of adult dosing, can be estimated as 25% for children <15 kg, 50% if 15-30 kg, 75% if 30-45 kg, and 100% if >45 kg.
Because the National Hansen's Disease Program may change its recommendation for patient management, clinicians in the United States are advised to seek consultation prior to treating any patient with leprosy (telephone: 1-800-642-2477 or 1-225-756-3709, or e-mail, Mtemplet@hrsa.gov; it also has a website available at www.bphc.hrsa.gov/nhdp/).
ND, No dosing information available; *NHDP,* National Hansen's Disease Program; *WHO,* World Health Organization.

can render a highly positive lepromatous patient noninfectious within 1 week. Available formulations include capsules (150 and 300 mg) and a parenteral formulation. The WHO recommends rifampin as part of multidrug therapy for all forms of leprosy. The dose for persons 15 years of age and older is 600 mg, with pediatric doses of approximately 10 mg/kg given as a single daily dose. Optimal doses for children with leprosy have not been reported. Adult doses range from 300 to 600 mg daily.[415] Many side effects and drug–drug interactions with rifampin have been described, and the relevant literature must be consulted.[36] Rifampin-resistant leprosy has been reported,[144,402] so monotherapy with rifampin is not recommended. Rifampin is not felt to interact with dapsone or clofazimine.

Clofazimine

Clofazimine (Lamprene) is a bacteriostatic riminophenazine dye that has anti–*M. leprae* and anti-inflammatory activities, of particular utility for patients with erythema nodosum leprosum reactions, and is part of multidrug therapy for multibacillary leprosy (in conjunction with dapsone and rifampin).[93] The mechanism of action may involve enhancement of oxygen-dependent killing of *M. leprae* and binding to bacterial DNA. Clofazimine is available in 50- and 100-mg capsules, but is not commercially available in the United States (the National Hansen's Disease Program [NHDP] can facilitate U.S. practitioners obtaining the medication). The WHO recommends clofazimine for patients with multibacillary leprosy.[411] The lower dosages are used for maintenance therapy when a good clinical response has been achieved, and the higher dosages (up to 100 to 300 mg daily in two or three divided doses) may be needed to control erythema nodosum leprosum; these regimens have not been well-studied in children. The major side reactions to clofazimine are hyperpigmentation of skin and enteritis. Enteritis is experienced only at the higher dosages generally used for erythema nodosum leprosum. The pink to

black hyperpigmentation is most prominent on exposed body parts, usually begins within 1 to 4 weeks of therapy initiation, subsides with the clinical improvement in leprosy, and resolves after drug withdrawal. Pigmentary staining of the cornea and lacrimal fluid have been reported, but infrequently affects visual acuity. Although two instances of clofazimine-resistant *M. leprae* infection have been reported, the validity of these observations is uncertain.[165,393] Cross-resistance between clofazimine and dapsone or rifampin has not been reported. For some time, clofazimine has been considered safe in pregnancy, but one report described three neonatal deaths in 15 observed pregnancies.[94] Whether the drug was associated with the deaths was not established. Monotherapy with clofazimine is not recommended.

Multidrug Therapy

Because of the existence of drug-resistant *M. leprae*, combined drug regimens are mandatory for the treatment of all forms of leprosy.[89,330,394,395] The first large-scale multidrug therapy for leprosy was initiated in Malta in 1972. Rifampin, dapsone, prothionamide, and isoniazid were used. Evaluation of the patients approximately 20 years later revealed a single relapse; however, presumed "persisting" *M. leprae* organisms were detected.[108,157]

Combined drug therapy minimizes development of drug-resistant strains of *M. leprae* and may eliminate some "persisting" organisms. Persisting *M. leprae* are viable bacilli that can be isolated in small numbers from patients who are clinically responding well to therapy. These persisting *M. leprae* bacilli are sensitive to the drug in question when tested in the mouse footpad and may account for relapses when treatment is discontinued. Persisting *M. leprae* organisms have been detected after 5 years of therapy with rifampin, 6 years of clofazimine therapy, and 22 years of dapsone therapy.

In 1982, a WHO study group recommended the multidrug therapy regimens that are described hereafter.[406] The multidrug therapy regimens were designed primarily for field programs, and they use pulsed supervised monthly rather than daily rifampin.[19] Multidrug therapy is well tolerated, and compliance in large-scale control programs has been satisfactory. The efficacy of multidrug therapy has been promising.[42,395] In two surveys involving approximately 112,000 patients with multibacillary disease monitored for 9 years after receiving therapy, the cumulative risk for relapse was 0.77 percent. Anecdotal descriptions of certain groups of highly bacilliferous patients with relapse rates of 20 percent and recurrences developing 5 years or more after therapy have been reported.[146] These and other results suggest that therapeutic regimens for multibacillary patients should be given for longer than 2 years. In most reports, relapse rates in paucibacillary patients exceed those in multibacillary patients. The potential for relapse after receiving multidrug therapy regimens must await long-term, large-scale follow-up results.[145,342] One study indicated that IgG antibodies against several recombinant leprosy proteins (including PGL-1) decline during therapy and may serve as a marker for disease recurrence.[85] Peripheral neuropathy sometimes persists after completion of these therapeutic regimens.[4,130]

The trend since 2001 has been to reduce the duration of treatment and change the therapeutic regimens—even to the extreme of a single-dose regimen composed of rifampin, ofloxacin, and minocycline (ROM) for single-lesion therapy. One meta-analysis concluded that single-dose ROM was less effective than multidrug therapy for paucibacillary leprosy.[322] Many of these innovations are interwoven into the WHO Elimination of Leprosy Program and have provoked critical concern by some authorities.[100,193,248,344] The NHDP recommends daily therapy,[252] as opposed to the intermittent dosing recommendations for rifampin recommended by the WHO for resource-limited settings. Both WHO- and NHDP-recommended regimens are listed in Table 98-2. Laboratory monitoring should include baseline complete blood count, transaminases, bilirubin, blood urea nitrogen, creatinine, and calcium and then repeated every 3 months.

Other Drugs Under Investigation

Recent years have seen escalating use of fluoroquinolones, macrolides, tetracyclines, and ethionamide for patients intolerant of standard regimens.[112,113,123,148] Knowledge of the *M. leprae* genome will potentially lead to targeted drug development after computational genomic analysis. For example, one study identified several genes mapping to peptidoglycan cell wall biosynthesis; these *Mur* genes have no homolog to human genes, decreasing the risk for cross-reactivity of agents.[325]

Treatment of Reactions

Patients experiencing a reaction should be observed daily in the early stages and hospitalized if the symptoms are severe. Formerly, specific therapy was stopped or the dosage reduced during reactions, but these measures are no longer recommended.[406] Damage to eyes and neurotropic changes may ensue rapidly without immediate attention. Nerve tenderness and function must be assessed frequently during reactions. Acute inflammation of isolated lesions without damage to nerves is likely to be of little consequence except for cosmetic considerations, but the patient should be monitored closely.

Reversal (Type 1) Reaction

Patients with painful, tender nerves must receive immediate care, usually in the hospital. Analgesics are given, and the affected area is rested. Large daily doses of corticosteroids are started and tapered to a minimal effective dose until the reaction subsides. Conversion to alternate-day steroid regimens may be attempted when long-term treatment is necessary. One randomized, double-blind trial compared methylprednisolone with placebo in conjunction with oral corticosteroids for adults with type 1 reactions; persons treated with methylprednisolone were less likely to have nerve damage and recurrent type 1 reactions.[384] However, one meta-analysis indicated that although corticosteroids may be useful for treating acute

nerve damage, long-term benefit may not be seen.[41,374] A 12-week course of topical tacrolimus was used in one case of steroid-refractory type 1 reaction in a child with borderline lepromatous leprosy, with resolution of all skin lesions.[302] Some clinicians use clofazimine for chronic reversal reactions, but it is not recommended for the initial treatment of reactions with acute neuritis. For reactions, clofazimine probably is consistently efficacious only for erythema nodosum leprosum.[140]

Erythema Nodosum Leprosum (Type 2) Reaction

Mild erythema nodosum leprosum is treated with analgesics; more severe disease is treated with thalidomide or corticosteroids.[381] Pediatric doses of thalidomide in erythema nodosum leprosum have not been established, but the initial adult dose is 100 mg four times daily followed by a minimal effective dose, usually 100 mg daily. In the United States, thalidomide is available for erythema nodosum leprosum under the Calgene S.T.E.P.S. Program.* The teratogenic action of thalidomide demands that appropriate measures be taken in the treatment of fertile women. For the rare patient who does not respond to thalidomide or in fertile women, corticosteroids or clofazimine is used. Corticosteroids, if used, are administered in the usual dosage schedules (1 to 2 mg/kg daily), beginning with large doses and tapering to a minimal effective level. One systemic review indicated that clofazimine was superior to thalidomide or corticosteroids, but analysis was hindered by variation in the quality of studies in the pooled data.[373] Clofazimine is effective in most patients with erythema nodosum leprosum and does not have the disadvantages of thalidomide or corticosteroids. The anti-inflammatory action of clofazimine is not manifested until after 4 to 6 weeks of continuous use. The dosage must be adjusted to the minimal effective level, and high doses are recommended by the WHO for erythema nodosum leprosum reactions.[411] A few studies suggest that pentoxifylline or pentoxifylline plus clofazimine is effective.[255,357,397] One case report described the successful treatment of a chronic erythema nodosum leprosum reaction with a 6-week course and slow taper of the TNF inhibitor etanercept.[277]

Iridocyclitis requires emergency measures. Local corticosteroids must be added to systemic anti-inflammatory regimens. Ophthalmologic consultation should be obtained.

PREVENTION

Precise recommendations for the prevention of leprosy in individuals have not been formulated. Control programs today are based on the general principles that (1) the number of contagious patients is reduced by chemotherapy and (2) the surveillance of contacts detects early leprosy. To accomplish these goals, appropriate education of the public and medical personnel and population surveys in areas of higher prevalence must be implemented. In endemic areas, improved housing probably is a highly important preventive measure by reducing close contact of patients with healthy individuals. In health care settings, infection control precautions include hand hygiene for all patients with lepromatous leprosy. Standard precautions are indicated for the hospitalized patient. Leprosy is a reportable disease in the United States.

Chemoprophylaxis

Chemoprophylaxis for close contacts was first attempted with dapsone, showing efficacy rates ranging from 34 to 99 percent,[342] but was not recommended for large populations[67] given concerns that long-term use would select for dapsone-resistant isolates.[415] More recently, rifampin has been evaluated for chemoprophylaxis. One study on leprosy hyperendemic Indonesian islands used rifampin every 3.5 months, showing protective efficacy of 75 to 90 percent.[10] A cluster randomized trial in Bangladesh showed that single-dose rifampin had protective efficacy of 57 percent within 2 years of administration.[238] Single-dose rifampin chemoprophylaxis has been shown to be both culturally acceptable[95] and cost effective, particularly in social contacts and neighbors of cases.[139] However, concern exists that single-dose rifampin chemoprophylaxis may select for rifampin-resistant *M. leprae* isolates.

Vaccination, Immunoprophylaxis, and Immunotherapy

M. leprae antigens for vaccines originally were obtained from experimentally infected armadillos. Vaccines composed of heat-killed whole *M. leprae* have been found to be safe and to induce delayed-type hypersensitivity to *M. leprae* in a high percentage of lepromin-negative individuals. Several other vaccines based on cultivable mycobacteria (*Mycobacterium vaccae*, *Mycobacterium "w,"* and the Indian Cancer Research Centre bacillus) induce similar responses.[21,166,347] Field trials of these vaccines for the immunoprophylaxis of leprosy have been conducted; however, because of the chronicity and low prevalence of the disease, meaningful evaluation of their efficacy would require extended follow-up observations.[23] Because infection-induced immunity is not observed regularly in leprosy, a reasonable doubt exists that vaccines containing only *M. leprae* would be protective. Consequently, combined vaccines of killed *M. leprae* and live bacillus Calmette-Guérin (BCG) have been studied. Such vaccines convert lepromin-negative contacts of patients with leprosy to positive reactors and upgrade patients with lepromatous leprosy toward the tuberculoid region of the disease spectrum.[53,222]

BCG immunization alone had a protective effect of 26 percent in one meta-analysis; this analysis also found that age at immunization did not affect efficacy and that receipt of a second dose of BCG vaccine was more protective for leprosy than receipt of a single BCG dose.[323] Heterogeneity among trials and overestimation of

*Calgene S.T.E.P.S. Program: 1-888-771-0141.

protective effect (61%) was seen in observational studies in contrast to experimental studies.[323] Large-scale studies in Malawi and Venezuela suggested that the addition of killed *M. leprae* to BCG did not protect against leprosy.[55,167] BCG vaccination was combined with single-dose rifampin for close contacts of leprosy patients in Bangladesh, showing a protective effect of 80 percent.[313] The WHO does not recommend BCG vaccination for the prevention of leprosy.[18] This decision was based on the highly variable results of extensive studies in Burma, Papua New Guinea, and Uganda.[406]

Leprosy vaccines as adjuvant to multidrug therapy also have been attempted in multibacillary leprosy patients. *Mycobacterium w* vaccine given in 3-month intervals (up to 8 doses) was associated with improvement in clinical scores and decline in bacteriologic indices for up to 2 to 3 years, but no impact was seen on clinical relapse or incidence of neuropathy after this interval. Rates of type 1 reactions were more common in the vaccine group in contrast to a placebo group receiving multidrug therapy alone.[326]

ELIMINATION

In 1991, the World Health Assembly defined leprosy elimination as a prevalence of fewer than 1 case/10,000 persons. By this definition, only three nations with populations over 1 million have yet to attain this goal: Brazil, Nepal, and Timor-Leste (East Timor).[38] The prospect of truly eliminating leprosy is poor due to several factors. First, a zoonotic focus[219,365] can lead to continued introduction into human populations. Second, vaccination development efforts have been hindered by poor correlates of immunity. Third, surveillance for new cases can be hindered by the stigma attached to the disease. This can lead to either failure to seek medical attention or seeking medical attention in alternative medical settings, where reporting of cases may not occur.[143] One study modeled the impact of various interventions on leprosy incidence rates. Variables included passive versus active case detection, multidrug therapy, contact tracing, BCG vaccination of infants, early diagnosis of subclinical infection, and chemoprophylaxis. A multifaceted approach including BCG vaccine coverage, contact tracing, early diagnosis, and chemoprophylaxis of household contacts seemed to most substantially reduce leprosy incidence rates.[101] However, these strategies would require an infrastructure and investment that fall outside the health budgets of many developing nations. Given the lack of tools to diagnose subclinical infection, long treatment duration, and continued uncertainty regarding aspects of patterns of exposure, modes of transmission, persistence of leprosy in treated cases, and early host response, many experts believe that control, rather than eradication, should be the goal.[341]

BURULI ULCER

Mycobacterium ulcerans causes indolent, necrotizing cutaneous ulcers that are known classically as *Buruli ulcers*.[195,371] They are named after the county in Uganda, near the Nile, where the first large epidemic was described in 1897.[46,56,77] Other names for these lesions include Bairnsdale or Searles ulcer in Australia and Kumusi ulcer in Papua New Guinea. Today, researchers recognize that many infections with *M. ulcerans* are not manifested as ulcers and *M. ulcerans* infection is a technically more appropriate name for the disease. A few infections have been acquired by travelers returning from endemic areas,[50] as well as patients from endemic areas referred to medical centers in industrialized countries.[274]

The WHO has recognized Buruli ulcer as a reemerging infectious disease in western Africa with an important public health impact. The WHO Global Buruli Ulcer Initiative has held annual meetings to evaluate all aspects of the disease since 1998, and in 2004 the World Health Assembly adopted a resolution for all member states to intensify research to develop tools for diagnosing, treating, and preventing Buruli ulcer.[408]

ORGANISM

MacCullum and associates[196] in 1948 in Australia were the first to isolate the etiologic agent in culture. *M. ulcerans* is strongly acid-fast, with an optimal growth temperature of 30° to 33°C (86° to 91.4°F) on routine mycobacteriologic media such as Löwenstein-Jensen medium. Unlike *M. marinum*, *M. ulcerans* is slow-growing, nonphotochromogenic, microaerophilic, and heat sensitive.[223,263]

Comparative genomic analysis indicates that *M. ulcerans* arose from *M. marinum* via horizontal transfer of a virulence plasmid.[73] The two species have 98 percent genomic homology, but *M. ulcerans* has lost 1.1 Mb of DNA from the 6.6 Mb *M. marinum* genome.[354] However, differences in clinical manifestations between the two species are attributed in large part to one addition to the genome. *M. ulcerans* is the only mycobacterial pathogen of humans known to elaborate a necrotizing, immunosuppressive exotoxin, mycolactone.[62,282,336] The genomic sequences of the plasmid-encoded synthases that produce mycolactone have been described more recently.[352] The mycolactone mechanism of action is unclear, but evidence exists for the toxin triggering apoptosis[127,388] and decreasing satellite cell proliferation.[134]

Specific insertion sequences for *M. ulcerans* have been characterized and are available for identification of the organism by PCR.[1,335,353] Variations in the 3′ end of the 16S rRNA gene sequence are related to geographic origin and are used to divide the organism into African, American, Asian, and Australian strains.[272]

TRANSMISSION AND EPIDEMIOLOGY

Endemic foci of *M. ulcerans* infections usually appear in rural settings near permanent wetlands in warm countries, especially in terrain subject to seasonal flooding. Reports of patients with Buruli ulcers have come from at least 30 countries, principally in the tropics.[409] A few patients live in nontropical climates, such as China,[90] Japan,[364] and southern Australia.[376] Today, the largest numbers of reported patients live in West Africa (i.e., Benin, Côte d'Ivoire, and Ghana).[371] In these countries, the disease is reemerging rapidly, with an estimated total annual incidence exceeding 4000 patients. Other countries in which the disease is known to be endemic include Angola, Cameroon, the Democratic Republic of the Congo, Equatorial Guinea, French Guiana, Gabon, Indonesia, Malaysia, Papua New Guinea, Peru, Suriname, and Uganda.[69,132,215,268] In the Western Hemisphere, cases have been reported primarily in French Guyana, but also in Brazil, Mexico, Peru, and Suriname.[409]

Observers attribute this reemergence to environmental factors such as deforestation, artificial topographic alterations (e.g., dams and irrigation systems),[68,197] increasing populations engaged in basic manual agriculture in wetlands, and possibly climactic changes.[225] These man-made environmental modifications may lead to changes in water temperature or turbidity, potentially protecting *M. ulcerans* biofilms.[214] In North America, two cases of Buruli ulcer were reported in 2005 in central Mexico, the nearest location to the United States to date.[48] Individuals of all ages are affected, but the highest frequencies are in children 15 years of age or younger—approximately 50 to 75 percent of all cases.[201] A second peak occurs in the seventh to eighth decade of life, suggesting that latent infection can reactivate with age.[70] The sexes are affected equally, and a racial predilection is unknown.[70] Anecdotal observations of children in families of multiple parentage have suggested a possible genetic predisposition, now supported by molecular studies.[348] Seasonal variations in incidence occur in some foci.[129,284] Approximately 80 percent of the lesions are on the limbs, with the highest frequencies involving the lower extremities.

Although the ultimate source of *M. ulcerans* remains obscure, the organism has been discovered in aquatic insects, such as water bugs, firefly larvae, and beetles, and obtained from stagnant water in endemic areas of West Africa, as well as newly dammed areas in Cameroon.[197,200,271] In some cases, the organisms were found only in the salivary glands of aquatic insects, supporting the notion that insect bites may play a role in transmitting *M. ulcerans*.[198,199] Adult mosquitoes trapped outside Victoria, Australia also had detectable *M. ulcerans* DNA. *Aedes* spp. were most likely to have DNA identified, followed by *Anopheles* spp.; lowest detection was seen in *Culex* spp.[186] This may explain the observation that having daily contact with a natural water source was a risk factor for Buruli ulcer disease according to one study in Benin,[345] and that lower rates of Buruli ulcer were seen in higher altitude villages in Benin.[346] Wading into rivers was a risk factor for Buruli ulcer in one study, which also found that the most common lesions occurred on uncovered extremities[275]; both also suggest transmission from biting aquatic insects. A group from Melbourne, Australia, evaluated both environmental sources and nonhuman animal feces for *M. ulcerans* DNA. Real-time PCR detected DNA in soil, water residue, and aquatic and terrestrial vegetation in one endemic area. The group also found that 41 percent of opossum feces tested positive.[106] Koalas and small rodents also have been found to harbor *M. ulcerans*.[84,231] *M. ulcerans* DNA was not detected in fecal samples from Buruli ulcer patients, suggesting the human gastrointestinal tract is not likely to be a significant reservoir.[307] After the development of molecular biologic techniques for the identification of *M. ulcerans*, the organism was detected in the environment in Australia by IS2404 PCR.[295,296,350] However, these molecular assays do not detect only viable organisms, so some instances of detection from environmental sources may represent dead organisms sticking to environmental substrates.

Buruli ulcer rarely, if ever, is contagious. The distribution of patients, even in highly endemic foci, is random, suggesting that each patient is exposed to environmental sources, such as swamps where villagers work their gardens and obtain water for domestic use and especially where children play. The mode or modes of transmission to humans have not yet been delineated completely; however, the most plausible route is by trauma at sites of skin recently contaminated by *M. ulcerans*.[81,224] Many patients give a history of specific antecedent penetrating trauma at the site of their initial lesion, which may include wounds from a gunshot or land mine, thrown stones, hypodermic injection, or even a human bite (Fig. 98-14).[72] The organism may be spread by aerosol from the surface

FIGURE 98-14 ■ A major Buruli ulcer in the deltoid area of a 12-year-old Angolan boy. This pristine ulcer developed 3 months after a documented hypodermic anticholera vaccine injection at this site. Typical Buruli ulcer features are represented—undermining of borders, necrotic base, and induration of the adjacent skin. (See companion Expert Consult website for color version.)

of ponds or be carried by fomites or insects to skin surfaces. Insects may introduce *M. ulcerans* into the skin, but this means of transmission has not been proved. Although proposed by some authorities, transmission by nasorespiratory passage with a subsequent bacteremia seems to be unlikely.

PATHOGENESIS AND PATHOLOGY

Three properties determine the pathologic features of early *M. ulcerans* infection: optimal growth at 30° to 33° C (86° to 91.4° F), slow growth rate, and elaboration of the toxin mycolactone.[336] The temperature requirement tends to favor the development of lesions in the skin (versus deeper tissues). The slow growth rate results in slowly progressive lesions. Mycolactone destroys tissues and suppresses immune responses. The spectrum of clinical and histopathologic forms of infection suggests that some patients have innate resistance, or resistance develops soon after infection is acquired, whereas others acquire resistance later or, occasionally, never.

Many of the differences in pathogenicity between *M. ulcerans* and *M. marinum* may be explained by the presence of mycolactone in the former species. Mycolactone has broad-spectrum cytotoxic activity for a variety of cell types. Necrosis is due in part to mycolactone triggering massive apoptosis, vasculitis, and thrombosis of subcutaneous and dermal vessels. However, most studies have evaluated mycolactone levels in peripheral blood, and it is unclear to what degree this reflects concentrations in ulcerative lesions.[336] Mycolactone is also thought to inhibit TNF-γ and IL-2 production and augment IL-10 production.[3,60,177] Other pathogenic mechanisms may include *M. ulcerans* cell wall phospholipases, which have homology to *M. tuberculosis*.[118] These activities partly explain the immunologic unresponsiveness and reduced inflammatory reaction at the site of the lesion. One study in Benin found that the rate of hemoglobinopathies was almost seven times higher in Buruli ulcer osteomyelitis patients than the general population, suggesting these disorders facilitate the growth of the organism in bony matrices.[249]

Based on the current understanding of the natural history of *M. ulcerans* infection, pathogenesis may proceed as follows: after inoculation of the etiologic agent deep into the skin or subcutaneous tissue, a latent phase occurs during which the mycobacterium proliferates slightly, probably initially intracellularly,[261] and begins to elaborate small amounts of toxin that causes necrosis, especially of fatty tissue. This necrosis provides a microaerophilic environment and perhaps nutrients favorable for the accelerated growth of *M. ulcerans* and elaboration of increased amounts of toxin. During this necrotic phase, no significant cellular response occurs.[49,50,77]

In some patients, at this stage, a subcutaneous nodule begins to develop, with clusters of *M. ulcerans* in the center surrounded by a zone of necrosis. In highly resistant patients, this lesion may self-heal, perhaps without ulceration, or form a small, sharply delineated ulcer. In others, the skin is undermined by the necrosis and eventually breaks down into larger ulcers with widely undermined skin. In the least resistant individuals, a nodule never develops and the necrosis spreads rapidly and widely to cover large body surface areas, but ulceration, if it occurs at all, is a late event.

Eventually, the necrotic stage ceases in most patients, either because the toxin is neutralized or because production is interrupted. At this time, a granulomatous stage begins to develop, followed by healing and scarring. Some of the variability in clinical presentation and progression of the disease may be related to heterogeneity in the *M. ulcerans* genome and in the plasmid that encodes the production of mycolactone.[1,246,351,355]

Microscopically, the active ulcer shows extensive coagulation necrosis of the subcutaneous tissue down to and often including the fascia (Fig. 98-15).[124] The deep layers of necrosis reveal masses of acid-fast bacilli, often with mineralization and extensive vasculitis. Marked edema is present, and fat cells enlarge and die, with only their cellular ghost outlines remaining (Fig. 98-16). The dermis and surrounding tissue seldom contain acid-fast bacilli. Lesions sometimes provoke a reactive (contiguous)

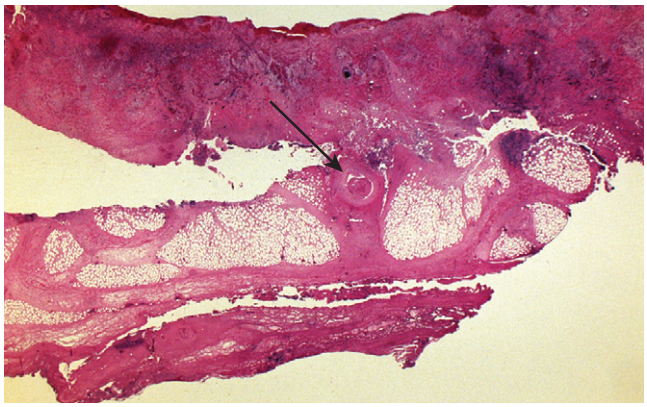

FIGURE 98-15 ■ Histopathologic section of the undermined edge of a major Buruli ulcer. Note the coagulation necrosis of the entire panniculus and fascia, and vasculitis with thrombosis of a blood vessel *(arrow)* (hematoxylin and eosin stain). (See companion Expert Consult website for color version.)

osteitis that leads to necrosis of cortical bone and osteomyelitis. Metastatic lesions may develop in the skin and bone from bacteremia and produce skin lesions distant from the original lesion and frequently focal or multifocal osteomyelitis. Regional lymph nodes may show massive necrosis and contain large numbers of acid-fast bacilli, especially in the capsule. Visceral organs are not known to be involved, but no necropsies of patients who died of disseminated disease have been reported.[359]

An understanding of the pathogenesis and developing improved therapies for Buruli ulcer has been slowed by the lack of an experimental animal model that replicates the spectrum of features found in human disease. Laboratory rats and mice develop skin lesions after intradermal inoculation with *M. ulcerans*, but they lack the extensive ulceration found in human disease. Multimammate rats *(Mastomys natalensis)* rapidly develop systemic infections and die.[338] In the mouse footpad, *M. ulcerans* multiplies, but necrosis without ulceration destroys the limb and causes death.[282] Guinea pigs develop inflammatory lesions at the inoculation sites that may resolve without formation of ulcers.[178,282] The nine-banded armadillo is susceptible to *M. ulcerans* and develops cutaneous lesions after experimental intradermal infection, approximating those of the human disease, but is phylogenetically distant.[387] The cynomolgus monkey (crab-eating macaque) is moderately susceptible to experimental *M. ulcerans* infection and develops some of the clinical and histologic features of Buruli ulcer.[382,385]

CLINICAL MANIFESTATIONS

Incubation and Forms of Lesions

In one study of specific trauma related to lesions, the incubation period ranged from 2 weeks to 3 years, with a mean of 3 months.[224] The following are the various forms of lesions of *M. ulcerans* infection according to WHO designations.[413] Figure 98-17 presents a proposed classification of the clinical forms of *M. ulcerans* disease and their possible interrelationships. The WHO also designates three categories of lesions. Category I consists of single lesions less than 5 cm in diameter; these may heal completely with medical therapy. Category II consists of a single lesion 5 to 15 cm in diameter; only some heal completely with medical therapy. Category III lesions encompass large (>15 cm diameter) lesions, lesions in multiple locations, osteomyelitis, or lesions in critical sites (e.g., ocular, genitalia, or breast). These lesions usually require combined medical and surgical therapy.[409,410]

Papule

The papular stage has been described only in patients from Australia. These papules are painless, elevated, and measure up to 1 cm in diameter.

Nodule

Nodules are primarily subcutaneous and firm, measure approximately 2 cm in diameter, and are painless, although they are often pruritic. The overlying skin may be discolored. Although usually mobile, they can become attached both to the skin and to deeper tissues.[366] This stage is the initial one in most Africans, and in the Kikongo language, the disease is called *mputa matadi* because the nodule is a "rock-hard lesion." Unlike ulcerative forms, acid-fast bacilli are aggregated in the center of nodules.[366] Nodular lesions have fewer functional limitations than other forms of Buruli ulcer disease.[312]

Plaque

Plaques are firm, elevated, painless, well-defined lesions more than 2 cm in largest dimension. Their borders are irregular. This stage often is the one in which physicians initially see the patient, but the lesion may or may not arise from a nodule. The skin over the lesion is reddened or discolored. These lesions may ulcerate in the late stages. These lesions are more likely to relapse after surgical therapy than ulcerative forms.[176]

Edematous Form

Most edematous lesions do not begin in the nodular stage but spread directly from the initial nidus of infection.

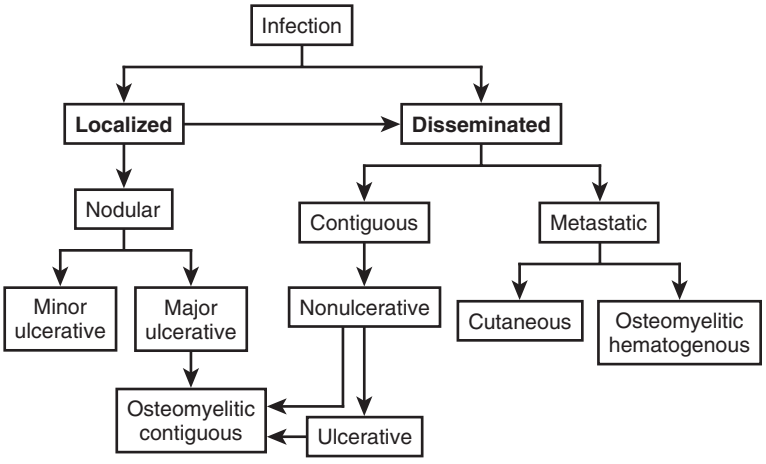

FIGURE 98-17 ■ Proposed classification of clinical forms of *M. ulcerans* infections, indicating possible progression of lesions after the initial cutaneous infection. Without treatment, lesions may self-heal at any stage, or advance according to the schema shown at left.

FIGURE 98-18 ■ Edematous form of *M. ulcerans* infection in a 6-year-old Ghanaian girl after surgery to remove all necrotic tissue. There was never any ulceration. Note ablation of breast tissue. (See companion Expert Consult website for color version.)

Spread often is rapid and wide and covers entire limbs or major portions of the trunk (Fig. 98-18). This type of lesion is characterized by diffuse nonpitting swelling and vague margins. Lesions are firm and frequently painful, with changes in color and scaling on the skin surface. These lesions, along with plaques, are more likely to relapse after surgical therapy than ulcerative forms.[176]

Ulcerative Forms

When fully developed, pristine ulcers have undermined edges surrounded by a zone of induration and often desquamation of the epidermis (see Fig. 98-14). In the base of the ulcerated area, a whitish necrotic slough and sometimes eschar develop. An oily exudate frequently oozes from the dependent area. Old ulcers tend to begin healing in the uppermost part while activity continues in the dependent portion. Collections of fluid in this area probably continue to support the growth of *M. ulcerans*, which sustains progression of the lesion.

The ulcerative forms are divided into major and minor ulcers. Both forms tend to self-heal. A major ulcer is large and chronic and can form a contiguous osteomyelitis. Minor ulcers are small (1 to 2 cm in diameter), are sharply delineated, and heal early. Both ulcerative forms begin as subcutaneous nodules.

Bone Involvement

Contiguous Osteomyelitis

Reactive osteitis occasionally develops beneath destroyed overlying skin and soft tissue, particularly with major ulcers. Bone becomes devitalized and necrotic, with the development of sequestra (Fig. 98-19).

Metastatic Osteomyelitis

M. ulcerans–specific osteomyelitis develops in approximately 10 percent of all patients, underscoring that Buruli ulcer should always be considered a potentially systemic disease.[274] Most likely, metastatic osteomyelitis is a result of lymphohematogenous spread of *M. ulcerans* from a distant, earlier cutaneous lesion (Fig. 98-20). The overlying skin ordinarily is intact, but swelling and inflammation occur over the site of bone involvement. If the

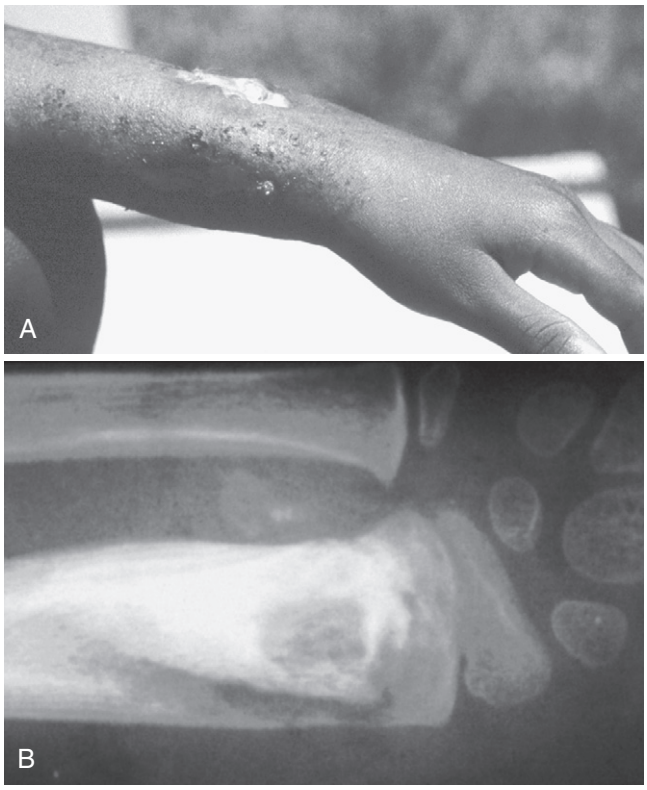

FIGURE 98-19 ■ **A,** *M. ulcerans* infection in a young Congolese boy. Note swelling and ulcer on dorsum of forearm. (See companion Expert Consult website for color version.) **B,** Radiograph of forearm shows reactive osteitis, necrosis of cortex of distal end of the radius, and early sequestration with osteomyelitis.

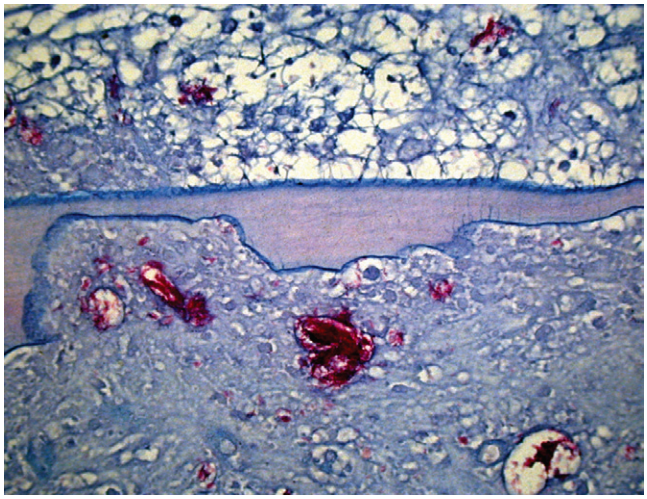

FIGURE 98-20 ■ Ziehl-Neelsen–stained section shows metastatic osteomyelitis of the tibia in a 6-year-old boy in Benin. This lesion developed after *M. ulcerans* infection of the contralateral leg. Note necrosis of marrow, erosion of a trabecula, and many clusters of acid-fast bacilli. (Ziehl-Neelsen stain). (See companion Expert Consult website for color version.)

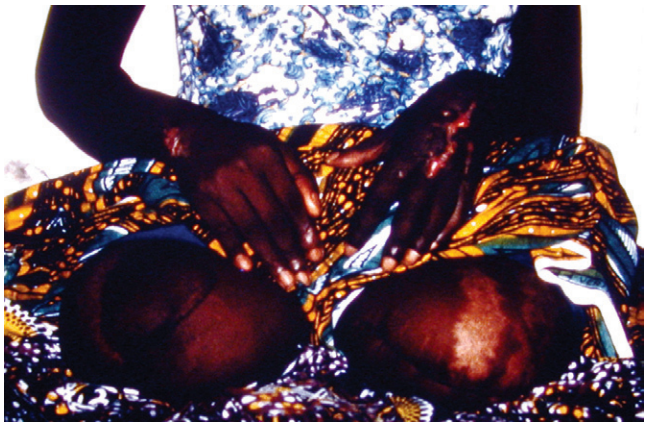

FIGURE 98-21 ■ This 13-year-old girl in Benin initially had a cutaneous lesion of Buruli ulcer. Subsequently, metastatic spread to bones of the lower extremities occurred, resulting in bilateral high-thigh amputations. Note also the spread to bones of both wrists and left hand. (See companion Expert Consult website for color version.)

FIGURE 98-22 ■ Ghanaian adolescent girl with healed *M. ulcerans* infection that extended from the wrist to the shoulder. The scarring resulted in contraction deformities of the wrist and elbow and disuse atrophy of the entire extremity. Appropriate physiotherapy would have minimized these sequelae. (See companion Expert Consult website for color version.)

condition goes untreated, a draining fistula usually develops. Osteomyelitis often requires amputation (Fig. 98-21).

Complications

Infection may traverse the deep fascia and damage tendons, nerves, joints, genitalia, and periorbital tissues, requiring subsequent enucleation of the eye. Healing leads to fibrosis and scarring, causing functional limitations.[349] The scar may form keloids and often causes major contraction deformities, especially in lesions that cross joints (Fig. 98-22). Squamous cell carcinoma may develop in healed lesions, especially nonpigmented lesions.[169] Skin grafting and physiotherapy prevent most of these complications. Most disease-related deaths result from septicemia, gas gangrene, or tetanus.

HUMAN IMMUNODEFICIENCY VIRUS AND BURULI ULCER

Because Buruli ulcer primarily is a disease of children in rural areas, very few patients have been reported with Buruli ulcer and HIV infection.[8,175] One study in Benin suggested that HIV infection increased the odds of Buruli ulcer eightfold.[154] Relevant reports indicate, however, that HIV infection may render Buruli ulcer disease highly aggressive; rapidly spreading *M. ulcerans* osteomyelitis has developed in several patients with AIDS.[175,303] Chronic diarrhea in an HIV-infected adult has also been attributed to *M. ulcerans*.[135]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

To an experienced observer, an accurate clinical diagnosis often can be made with ease.[414,416] In the ulcerated forms, a Ziehl-Neelsen stain of exudate from the ulcer edge obtained with a cotton swab reveals clusters of extracellular acid-fast bacilli. Punch biopsies and fine needle aspiration also have been used to obtain samples from nonulcerative lesions.[410] Smears have an estimated sensitivity of 40 percent.[409] The same material, obtained by swab after decontamination, may be used for culture on Löwenstein-Jensen or other suitable mycobacterial media. The incubation temperature must be 30° to 33° C (86° to 91.4° F). If culture cannot be performed locally, transport media may be inoculated with material from the cotton swab and maintained at 4° C (39.2° F) while in transport to a specialized laboratory. The transport medium is composed of Middlebrook 7H9 broth supplemented with polymyxin B, amphotericin B, nalidixic acid, trimethoprim, azlocillin, and 0.5 percent agar. Cultures often require at least 6 to 8 weeks to grow and have a sensitivity of 20 to 60 percent, in part because of the fastidious temperature requirements of the organism.[409] PCR is available and increasing in popularity and convenience.[1,335,350] PCR sensitivity is high (~98%).[409] Tissue for histopathologic analysis should be obtained from the edge of the ulcer and must include all levels, including the fascia. Fixation in 4 percent buffered formalin is adequate. Histopathology has a sensitivity of 90 percent in experienced hands.[409] Mycolactone can be found in peripheral blood and ulcer exudates (including exudates obtained at the conclusion of therapy) by high-performance liquid chromatography. This modality may have potential for diagnostic testing and stratifying risk for disease recurrence in the future.[308]

Some of the differential diagnostic possibilities are as follows:

- *Papules:* Insect bites, verruca vulgaris, pityriasis, granuloma annulare
- *Nodules:* Lipoma, sebaceous cyst, onchocerciasis, furuncle
- *Plaques:* Leprosy, mycosis, necrobiosis, psoriasis
- *Edema:* Bacterial cellulitis, actinomycosis, elephantiasis, pyomyositis
- *Ulcers:* Tropical phagedenic ulcer, noma, stasis ulcer, leishmaniasis

PROGNOSIS

Without treatment, Buruli ulcer often leads to deforming depressed scars, contraction deformities, or amputation. One study found that almost 60 percent of patients had functional limitations a median of 4 years after completing therapy. Functional limitations and risk factors for stopping work or school were collinear and included lesion over a joint or on hands or feet, female sex, older age, and presence of a persistent wound.[349] The stigma of the deformities and the socioeconomic burden of the disease often are marked.[9] With early appropriate treatment, including excision and grafting, the prognosis usually is excellent. Metastatic lesions and local recurrences occur frequently enough, however, to warrant vigilant follow-up.[6] Paradoxical worsening of lesions while on appropriate antibiotic therapy has been noted, similar to immune reconstitution inflammatory syndromes seen for other mycobacterial infections. These are thought to be due to mycobacterial antigens and inflammatory cytokines released from clinically unrecognized bacterial foci.[298]

TREATMENT

Treatment options for Buruli ulcer include antibiotics and surgical intervention, the latter commonly used for category III lesions. In the preantibiotic era, wide local excision was commonly used.[366] The WHO now recommends surgery as an adjunct to medical therapy, particularly to remove necrotic tissue, cover skin defects, and correct deformities resulting in functional limitations.[410]

The WHO recommends an 8-week course of rifampin 10 mg/kg (maximum 600 mg) daily and either streptomycin or amikacin 15 mg/kg (maximum 1 g) daily as first-line therapy for all forms of active disease.[410,411] Intramuscular administration of aminoglycosides in children may be limited by the small muscle mass in many children. Monitoring for side effects is essential. For streptomycin, treatment should be stopped if hearing impairment or vertigo with nystagmus develops. For rifampin, treatment should be stopped if hepatitis, jaundice, or acute renal failure occurs, side effects that generally are associated with intermittent therapy of more than 10 mg/kg. One randomized trial in Ghana for patients with ulcers less than 10 cm in diameter compared the WHO-recommended regimen to streptomycin and rifampin for 4 weeks, followed by rifampin and clarithromycin for 4 weeks; they found no difference in response to therapy acutely or at 1-year follow-up.[256] An entirely oral regimen of 8 weeks of rifampin and clarithromycin was evaluated in a pilot study of 30 Beninese patients with lesions less than 10 cm in diameter. The treatment was well tolerated, and all patients had healed by 12 months without disease recurrence.[43] The extent to which these studies would apply to patients with more invasive or multifocal disease is unclear. Mouse models have evaluated the activity of other agents against *M. ulcerans*, showing that 8-week regimens of rifampin with either moxifloxacin or linezolid displayed bactericidal effects and clinical response comparable to those of rifampin with an aminoglycoside.[149] Although this study is promising, linezolid may be cost-prohibitive in many resource-limited nations, and the use of fluoroquinolones in countries with high rates of tuberculosis also is of concern.

If surgical intervention is chosen, to minimize the danger of development of *M. ulcerans* bacteremia many surgeons prescribe clarithromycin and rifampin 1 to 2 weeks before performing surgery and have the patients continue antibiotic therapy for several weeks after surgery. Although reasonable, this antibiotic complement to surgery is not of proved efficacy. Papules and preulcerative nodules seldom are diagnosed, even in endemic areas; however, wide excision and primary closure usually are curative.[366]

Plaques and edematous forms are excised widely down to the fascia, or through the fascia if it is necrotic. Muscle usually is not damaged, but if so, the excision is extended into muscle. The lateral extent of excision often is difficult to determine. By careful palpation, the physician can establish an approximate limit of the disease. Exploratory incisions and blunt dissection may help determine the limit of induration and necrosis. Use of real-time PCR for determining the extent of disease is being evaluated.[291]

Very small ulcers can be excised and closed primarily, as for nodules. Large ulcers are excised widely. The required extent of surgery may be determined by exploratory lateral excision and blunt dissection. Split-skin autografting of surgical defects usually is performed after a bed of granulation tissue has formed. Postoperative care, including physiotherapy, should be designed to prevent contractures.

Bone lesions should be referred to specialists. Heat therapy without surgical excision has been successful for appropriate lesions, but must be applied assiduously, with all necessary controls.[223] Recurrences after surgical treatment are frequent, but rates are not well established.[71]

PREVENTION

In an endemic tropical rural setting where children usually are scantily attired, prevention of contamination of the skin from environmental sources is virtually impossible. Wearing long trousers seems to prevent development of infection.[201] Protected water supplies in villages would reduce exposure; however, such protective measures usually are futile in rural areas of developing countries. Standard precautions are indicated for the hospitalized patient. Buruli ulcer disease is not a reportable disease in the United States.

Vaccination with BCG has a moderate (40% to 50%) protective effect against *M. ulcerans* infections for 6 to 12 months,[138] although effect wanes with time and has been variable in both human and animal studies.[51] One form of Buruli ulcer disease for which BCG appears to have a sustained protective effect for children and adults is for the disseminated osteomyelitic form.[270] Studies also are evaluating whether repeated BCG vaccination may render the population more immune to *M. ulcerans* infection, although this was not seen in animal models,[270,358]

in contrast to what was found for leprosy.[167,323] One *M. ulcerans*–specific vaccine target would be mycolactone, but this polyketide is poorly immunogenic, and antimycolactone antibodies are not detected in either cases or controls.[51] Mycobacterial heat shock protein (HSP) 45 is very immunogenic and protective in mouse models, but homology to a human HSP increases risk for autoimmune reactions.[59] In the absence of an effective vaccine, control strategies have focused on early detection and treatment, combined with physiotherapy to reduce scarring and functional limitations.[409]

CHAPTER 99

Nocardia

Nada Harik • Richard F. Jacobs

Nocardia spp. are obligate aerobic bacilli that exist throughout the world as soil and dust saprotrophs. These organisms are non–spore-forming, thin, branching, gram-positive, partially acid-fast, filamentous bacteria. Humans become infected with *Nocardia* by two primary routes: inhalation of contaminated airborne dust particles or traumatic implantation of the bacterium into subcutaneous tissue. Pulmonary disease is the form of nocardiosis recognized most commonly in the United States.[2] The pulmonary event may be subclinical or transient, or it may provoke an acute or chronic process mimicking staphylococcal or fungal pneumonia, tuberculosis, or carcinoma. Hematogenous dissemination may occur, especially in immunocompromised hosts. The central nervous system is the most common site of dissemination, with involvement manifested most often as a brain abscess. Cutaneous nocardiosis may be acute, subacute, or chronic. This form of disease is seen predominantly in immunocompetent hosts, with *Nocardia brasiliensis* being the agent identified most frequently.

In 1888, Nocard, a veterinarian, noted an aerobic actinomycete in bovine farcy, a chronic wasting disease in cattle characterized by pulmonary abscesses and draining cutaneous sinus tracts. Eppinger first described human

disease in 1890. The earliest pediatric case was documented in 1895 in a boy with pulmonary and subcutaneous infection.[5]

ORGANISM

Nocardia spp. are included among the aerobic actinomycetes. They are gram-positive bacteria that are filamentous and branched and grow more slowly than other aerobic and facultatively anaerobic bacteria. They commonly produce a fungus-like mycelium that fragments or breaks up into rod-shaped and short coccoid forms. *Nocardia* spp. grow well aerobically on a variety of simple media (e.g., blood agar and brain-heart infusion agar); adding carbon dioxide (10%) promotes more rapid growth. The organisms are inhibited by antibiotics and antifungal agents, so media containing such agents do not support the growth of *Nocardia*. Because of their growth on commonly used fungal media (e.g., Sabouraud dextrose agar) and on some mycobacterial media (e.g., Löwenstein-Jensen medium), many *Nocardia* samples may be misdirected to the mycology or mycobacteriology section of clinical laboratories for identification.

In the past, microscopic and colonial morphology, biochemical tests, chemotaxonomic methods, or antimicrobial susceptibility patterns were used to speciate *Nocardia*. 16S rRNA gene sequencing and polymerase chain reaction (PCR) restriction fragment length polymorphism (RFLP) analysis are the current methods most frequently used for speciation; use of these molecular techniques has resulted in changes in the nomenclature of *Nocardia* spp.[11]

More than 30 species of *Nocardia* of human clinical significance have been identified.[11] Formerly the term *Nocardia asteroides* complex was used to account for the heterogeneity in antimicrobial resistance patterns seen among *N. asteroides*. Detailed molecular analyses and susceptibility testing have established clearly that *N. asteroides* complex represented many different *Nocardia* spp.[11] The most medically important species of *Nocardia* include: *N. asteroides*, *Nocardia abscessus*, *Nocardia brasiliensis*, *Nocardia farcinica*, *Nocardia brevicatena/paucivorans* complex, *Nocardia nova* complex, *Nocardia otitidiscaviarum* complex, *Nocardia pseudobrasiliensis*, and *Nocardia transvalensis* complex.

Nocardia spp. grow best at temperatures of 25°C to 45°C (77° to 113°F); growth at higher temperatures may be used for differentiation. In pure culture, small, chalky white, heaped, wrinkled, or verrucous colonies appear in 3 to 5 days. Mature colonies usually are light orange and have a velvety appearance caused by the production of rudimentary aerial mycelia. They have the odor of a musty basement or freshly turned soil. Detection of colonies from clinical specimens, such as respiratory secretions, may require 2 to 4 weeks. In mixed culture, rapidly growing bacteria may obscure small *Nocardia* colonies. Use of modified Thayer-Martin medium may enhance recovery.[46]

Gram stain of a portion of a colony shows delicate, branching filaments no more than 1 μm in diameter. The delicate filaments may fragment and produce bacillary or coccoid forms. Many *Nocardia* spp. are partially acid-fast (i.e., in contrast to *Mycobacterium* spp., they retain fuchsin less tenaciously). A modified Ziehl-Neelsen or Kinyoun stain that decolorizes with 1 percent sulfuric acid instead of the more active acid alcohol is best for showing acid-fast *Nocardia* in clinical specimens. Acid-fastness is characteristic of *Nocardia* in tissue or primary colonial isolates but is lost quickly on subculture; not all pathogenic strains of *Nocardia* are acid-fast.[6] *N. asteroides* often survives the *N*-acetylcysteine digestion procedure (without sodium hydroxide) performed on sputum or bronchial washings; however, some positive sputum specimens may be rendered falsely negative.[44] Cultures of sputum and bronchial washings for isolation of *Nocardia* should be performed before and after the digestion procedure.

EPIDEMIOLOGY, TRANSMISSION, AND PATHOGENESIS

Nocardia spp. occasionally can be skin contaminants or upper respiratory tract saprotrophs.[23,51,60] Bronchial obstruction or decreased bronchociliary clearance predisposes to colonization.[51] The presence of signs and symptoms that correlate with nocardiosis can help ascertain the clinical significance of a positive *Nocardia* culture.

Most infections occur in the lungs, via inhalation, with dissemination to the central nervous system occurring in one third of affected patients. Although nocardiosis occurs in immunocompetent individuals, 70 percent of patients are immunosuppressed by medications or underlying disease.[2] The typical patient has compromised cellular immunity (secondary to steroids, organ transplantation, cytotoxic chemotherapy, chronic granulomatous disease, chronic alcoholism, diabetes mellitus, or human immunodeficiency virus [HIV] infection). Nocardiosis also is seen more commonly in patients with chronic pulmonary disease or a history of surgery or trauma.[41] Person-to-person communicability has not been a problem. Historically the incidence of nocardiosis in the United States has been estimated to be approximately 500 to 1000 new cases per year.[4] However, this number most likely is an underrepresentation given the marked increase in the number of immunocompromised individuals. In addition, nocardial infections can be difficult to recognize, resulting in underestimation of the true incidence of nocardiosis. Presumed nosocomial nocardiosis has been reported.

Cutaneous nocardiosis usually is an infection of immunocompetent hosts. *N. brasiliensis* is isolated from approximately 80 percent of cases of primary cutaneous or subcutaneous nocardiosis.[53] Traumatic implantation of *Nocardia* into deep subcutaneous tissue may result in an indolent condition termed *actinomycotic mycetoma* (to distinguish it from the eumycotic mycetomas caused by true fungi). Mycetoma is a chronic, progressive infection that can extend to underlying bone. Actinomycotic mycetomas usually involve the lower extremities or hands and typically are caused by *Actinomadura* spp., non–acid-fast aerobic actinomycetes, or *Streptomyces* spp. Actinomycotic mycetomas caused by *Nocardia* frequently involve the chest and back. Mycetomas, the cause of which may be *N. brasiliensis*, have been described in Mexican and

South American field workers. This *Nocardia* spp. also has been documented as an opportunistic pathogen prevalent in Florida, with a predilection for diabetics.[56]

In addition to the classic mycetoma, traumatic introduction of *Nocardia* spp. from soil may result in wound infections that occur after a more acute or subacute course. The organism can be introduced into the skin by tick[37] and other insect bites[20,47] or by a cat scratch[21,52] and result in cellulitis, pustules, or pyoderma; these conditions occasionally disseminate in immunocompromised individuals.[30,31] Posttraumatic endophthalmitis[22] and poststernotomy mediastinitis[61,69] have been described.

Nocardiosis previously was considered a rare disease in humans; however, it is being recognized more frequently.[44] It has been diagnosed in individuals of all ages (4 weeks to 82 years of age). Except in cases of cutaneous nocardiosis, almost all patients have one or more severe underlying diseases (e.g., lupus erythematosus, asthma, glomerulonephritis, ulcerative colitis, bronchiectasis, tuberculosis, rheumatoid arthritis, diabetes mellitus, or sarcoidosis) or are immunocompromised (e.g., steroids, organ transplantation, chemotherapy, chronic granulomatous disease, or HIV infection). Patients with lymphoreticular neoplasms and transplant recipients seem to be particularly at risk. In addition, the risk for acquiring infection is increased in patients with chronic pulmonary disease and in any patient who is receiving long-term corticosteroid treatment. Infliximab treatment also has been associated with the development of nocardial infection.[67] This catalase-positive organism is one of the five main pathogens seen in children with chronic granulomatous disease and can cause severe infection.[27] Although *Nocardia* is not a surveillance organism for acquired immunodeficiency syndrome (AIDS), patients with AIDS may contract nocardiosis.[28] In a review of all cases (n = 25) of nocardiosis at an urban adult teaching hospital from 1999 to 2004, 76 percent of patients with nocardiosis also were infected with HIV; all had CD4 counts less than 100 cells/mm^3.[13]

In a retrospective review of cases of pediatric nocardiosis admitted to Arkansas Children's Hospital, five children with nocardiosis were identified from more than 100,000 admissions in a 10-year period. Four of the five patients had received a transplant within the previous year. Three of these patients had pulmonary disease caused by *N. asteroides*, and one transplant recipient had skin involvement with *N. brasiliensis* at a central venous line site. One immunocompetent 5-year-old boy contracted central nervous system infection caused by *N. asteroides* 2 months after incurring a penetrating brain injury.[25]

N. farcinica is a medically important pathogen.[55,66] In a series of 200 cases of *Nocardia* infection reported by Wallace and associates,[66] the isolates designated *N. farcinica* were from patients with severe illness, 56 percent of whom had disseminated infections. *N. farcinica* isolates were characterized by increased resistance to antimicrobials, specifically third-generation cephalosporins. Evidence from mouse models indicates that *N. farcinica* seems to be more virulent than are other *Nocardia* spp.[18] Because the various species of *Nocardia* seem to have different pathogenicities, determination of the infecting species of *Nocardia* is important.

The immune response to *Nocardia* is multifaceted.[2] Neutrophils are mobilized to the site of infection and are the predominant cell type found in lesions. Neutrophils only inhibit the organisms, however, and limit the spread of infection until an adequate cell-mediated immune response develops or effective antimicrobial agents are administered. Immune T cells are vital in clearing *Nocardia* from the lung and preventing dissemination; many predisposing conditions for nocardiosis involve inadequate cell-mediated immunity. Activated macrophages induce cytotoxic T cells effective against *N. asteroides*. *Nocardia* may survive inside neutrophils and macrophages by inhibiting phagosome–lysosome fusion and production of catalase and superoxide dismutase, which inactivate the myeloperoxidase system. *Nocardia* organisms exhibit a differential ability to evade phagosome–lysosome fusion that depends on their state of growth, possibly related to specific cell wall mycolic acids detected only in log-phase cells.[3] Differential cell wall characteristics also may influence the ability of *Nocardia* organisms to exhibit specific organ tropism (e.g., the brain).[7] Antibody may play a role in host defense through enhancement of macrophage activities. Although antecedent conditions of nocardiosis frequently involve dysfunctional cellular immunity, other preconditions include neutrophil disorders (chronic granulomatous disease) and immunoglobulin disorders.

PATHOLOGY

The lesions of nocardiosis are suppurative, whether in the lung or in subcutaneous tissue, and they involve primarily proliferation of neutrophils rather than formation of granulomas. Pulmonary nocardiosis in immunocompetent patients often resembles pulmonary actinomycosis in that it results in a chronic localized pneumonia that often abuts the pleura.[26] Indolent progressive fibrosis resembling fibronodular tuberculosis may occur. Nocardiosis is more aggressive in immunocompromised patients and is manifested as multifocal necrotizing pneumonia with confluent abscess formation. *Nocardia* spp. tend to invade the pleura and chest wall, with tissue planes disregarded in the process. Little evidence of encapsulation is characteristic of all organs invaded and probably accounts for the ready dissemination of organisms from the initial pulmonary focus.

Nocardia spp. appear as delicate, beaded, branching filaments in tissue stained with Gram stain or modified acid-fast stain (Fig. 99-1). *Nocardia* spp. are invisible in hematoxylin and eosin preparations or in sections stained with periodic acid–Schiff for fungi. Methenamine silver preparations sometimes detect tissue organisms; overstaining with silver enhances visualization.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common manifestation of nocardiosis (>40% of all cases) in the United States is pulmonary disease in a patient with underlying immunosuppression.[16,49,51] Infection may remain localized to the lung or may

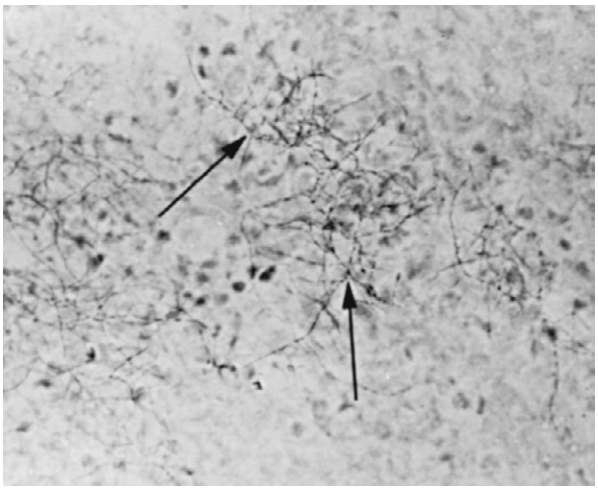

FIGURE 99-1 ■ Appearance of *Nocardia asteroides* and *Nocardia brasiliensis (arrows)* in a properly decolorized acid-fast smear. Organisms appear as fragmented bacilli with stain concentrated in a beaded fashion along portions of the filaments (×160).

disseminate hematogenously to the central nervous system and skin and, more rarely, to almost any organ in the body. In high-risk patients, the diagnosis should be suspected when central nervous system manifestations, particularly signs of a brain tumor, abscess, or soft tissue swelling, develop in conjunction with a current or recent subacute or chronic pulmonary infection. Although sulfonamides are the most effective drugs for treatment of nocardiosis, invasive infections have been described in immunocompromised individuals receiving oral trimethoprim-sulfamethoxazole (TMP-SMX) as prophylaxis for *Pneumocystis* pneumonia[14,63] and in patients with chronic granulomatous disease receiving TMP-SMX prophylaxis.[57]

Clinical manifestations of pulmonary nocardiosis are not specific and include anorexia, weight loss, productive cough, pleural pain, dyspnea, and, occasionally, hemoptysis.[16] Untreated pulmonary nocardiosis usually runs a chronic course, similar to that of tuberculosis, but it also may clear spontaneously and obscure the source of subsequent metastatic infection. The diverse clinical and radiographic manifestations, including acute bronchopneumonia, lobar pneumonia or necrotizing pneumonia with single or multiple abscesses, and pleural empyema, may mimic more common pulmonary infections, such as mycobacterial, staphylococcal, and fungal pneumonia. For example, common computed tomography (CT) findings of pulmonary nocardiosis include solitary or more often multiple lung nodules and lung consolidation with or without cavitation that are nonspecific.[32] Pleural involvement (i.e., thickening or effusion) and chest wall extension are seen less commonly on CT.[32] Normal hosts or patients with only slightly impaired host defenses may have only mild respiratory tract symptoms of several months' duration.[19]

The central nervous system is the most common secondary site of infection, and such infection occurs in one third of patients.[2] Most experts recommend performing routine cranial CT for patients with pulmonary nocardiosis even when they are asymptomatic because of the frequency of involvement of the central nervous system. Brain abscesses are the most common manifestation; meningitis is reported less frequently.[9,14]

Traumatic inoculation may result in localized disease manifested as cellulitis, subcutaneous abscess, or a lymphocutaneous syndrome in which one or more cutaneous nodules are associated with regional adenopathy or suppurative lymphadenitis.[36] Over a 5-year period, 31 cases of localized cutaneous nocardiosis with *N. brasiliensis* were identified in immunocompetent children in South Texas.[21] *Nocardia* spp. may cause cervicofacial disease and cervical adenitis in children.[35] Cutaneous nocardiosis can be mistaken for sporotrichosis, tularemia, mycobacterial infection, or superficial cellulitis.

Other reported clinical manifestations include tracheitis, peritonitis, iliopsoas abscess, hematogenous endophthalmitis, keratitis, endocarditis, mediastinitis, septic arthritis, ventriculitis and choroid plexitis, and osteomyelitis.[16,34,42]

Bacteremic nocardiosis is reported rarely and usually is associated with endovascular foreign bodies in patients receiving long-term steroid therapy.[33] Catheter-associated *Nocardia* bacteremia also has been reported in a child with acute lymphoblastic leukemia (ALL) on maintenance chemotherapy.[68] In a report of six cases of central venous catheter–related *Nocardia* bacteremia, four cases were in children 18 years or younger.[20] All six patients received antibiotic therapy; the catheter was retained in three of the six. Relapse occurred in one of the three patients in whom the catheter was not removed.[20]

The diagnosis of nocardiosis is established in one third of cases by sputum analysis and culture. Humoral methods used to diagnose nocardiosis generally lack specificity because of the high degree of serologic cross reactivity that occurs among *Nocardia* spp. and between *Mycobacterium* and *Streptomyces* spp.[8] The probable decreased sensitivity for detection of an antibody response in immunocompromised individuals also likely is a limitation of serologic testing. It is important to notify the laboratory when nocardial infection is suspected so that steps can be taken to optimize its recognition and recovery. Although *Nocardia* colonies usually are evident by 3 to 5 days after culture, prolonged incubation may be necessary.

Although *Nocardia* spp. sometimes can be respiratory saprotrophs, withholding therapy from immunocompromised patients when cultures repeatedly are positive is difficult. Bronchoalveolar lavage or lung biopsy may be required to establish the diagnosis. Although these procedures are invasive, given the overlap in symptoms with other infectious and neoplastic processes and potential for rapid progression of disease, bronchoalveolar lavage or lung biopsy should be considered early in immunodeficient patients to establish a definitive diagnosis. The demonstration of tissue invasion confirms active infection.

Tentative species identification of most *Nocardia* can be made by biochemical methods, chemotaxonomic methods, or antimicrobial susceptibility patterns. However, only *N. brasiliensis*, *N. farcinica*, and *N. pseudobrasiliensis* can be identified reliably by these methods.[11] Molecular confirmation (e.g., DNA probes, PCR and PCR-RFLP molecular analyses, DNA sequencing, pyrosequencing, and ribotyping) of species identification is

the method of choice. Molecular testing by hsp 65 PCR and 16S restriction enzyme analysis identifies more than 90 percent of currently recognized clinical species.[11] PCR assays for identifying *Nocardia* spp. are not yet commercially available.

TREATMENT AND PROGNOSIS

Sulfonamides have been the best-studied drugs for the treatment of nocardiosis.[54,57,65] In the United States, TMP-SMX, the only intravenous sulfonamide formulation available, has been the agent of choice for treatment of nocardiosis. TMP-SMX has been used successfully at doses of 15 mg/kg/day of TMP and 75 mg/kg/day of SMX, either parenterally or orally.[57,62,64] Few cases have been reported of failure of TMP-SMX therapy for the treatment of nocardiosis.[1,24,48,58] TMP-SMX resistance among *Nocardia* spp. has been documented. However, a study of sulfonamide resistance in isolates of *Nocardia* spp. from six major laboratories across the United States from 2005 and 2011 showed only 2 percent resistance to TMP-SMX or sulfamethoxazole.[10] The 2011 Clinical and Laboratory Standards Institute document on susceptibility testing of mycobacteria and other aerobic actinomycetes recommends that all clinically significant isolates of *Nocardia* spp. be tested for susceptibility to multiple antimicrobial agents.[15] No published prospective clinical trials have correlated in vitro susceptibilities with clinical outcome for nocardiosis. Susceptibility testing is the best available guide for selecting appropriate combination therapy and alternative therapies if sulfonamides fail or cannot be given because of patient intolerance or allergy.

No prospective randomized trials have established the optimal antimicrobial therapy for nocardiosis. Recommended antimicrobial therapy regimens are based on efficacy in animal models of nocardiosis and in vitro susceptibility and synergy testing.[11]

TMP-SMX as a single agent usually is sufficient for patients with cutaneous nocardiosis. Many infectious disease specialists administer empirical combination drug therapy, consisting of TMP-SMX, amikacin, and a carbapenem or third-generation cephalosporin, for patients with severe disease, central nervous system nocardiosis, or disseminated disease, and for immunosuppressed patients because of documented treatment failure and mortality associated with sulfonamide monotherapy in those settings.[39,44,58] Currently, no *Nocardia* spp. are resistant to amikacin and a β-lactam in vitro; the use of both (plus TMP-SMX) ensures that all clinical isolates would be susceptible to at least one other drug.[11] Antimicrobial therapy can be narrowed to two agents when results of in vitro susceptibility testing become available. Because antimicrobial resistance patterns vary by species, clinical isolates identified initially as *Nocardia* should be speciated further using molecular techniques. Children allergic to sulfonamides can be treated with amikacin and a carbapenem or third-generation cephalosporin.

The oxazolidinone linezolid is the first antimicrobial shown to be active in vitro against all clinically important *Nocardia* spp.[12] Linezolid, which is available for oral administration, has been used successfully to treat 11 patients with nocardiosis.[28,43] In one study, linezolid-associated hematologic toxicity was seen in three of six patients.[43] Peripheral neuropathy has also been observed in individuals with nocardiosis treated with linezolid.[29] Myelosuppression occurs more commonly in individuals receiving linezolid for longer than 2 weeks. Therefore the use of linezolid for nocardial infection is limited by the prolonged treatment required for nocardiosis.

Clinical experience with minocycline, the tetracycline with best in vitro activity against *Nocardia*, has been encouraging. Amoxicillin-clavulanic acid has been effective in treating infections with *N. brasiliensis*, commonly a β-lactamase producer.[64] However, a case of acquired resistance to β-lactamase inhibitor antibiotics has been reported.[59] Other species with susceptibility to amoxicillin-clavulanic acid include *N. abscessus* and *N. farcinica*, whereas isolates of the *N. nova* complex are ampicillin susceptible or intermediate but resistant to amoxicillin-clavulanic acid.[11] Susceptibility of some *Nocardia* spp. to fluoroquinolones has been reported. In an in vitro study gatifloxacin and moxifloxacin generally were more active than was ciprofloxacin against isolates of *Nocardia*, especially against isolates of *N. farcinica* and *N. brasiliensis*.[11] A patient with disseminated *N. farcinica* nocardiosis initially treated with aspiration, TMP-SMX, and imipenem had recurrence of brain lesions after a change to monotherapy with moxifloxacin despite in vitro susceptibility to moxifloxacin.[17]

Clinical improvement typically is seen within 7 to 10 days after initiation of appropriate therapy.[41] Patients with unchanged or worsening symptoms after receiving 2 weeks of therapy should be reassessed thoroughly. Intravenous antibiotic therapy may be changed to an oral regimen after at least 3 to 6 weeks if clinical improvement is noted. The variable and chronic course of nocardiosis precludes determining precise therapeutic end points. Metastatic lesions can appear during or after an otherwise effective course of sulfonamide therapy with maintenance of the recommended 100- to 150-μg/mL level in serum or plasma. Because the tendency for relapse or the late appearance of metastatic disease is a concern, therapy often is continued for many months. Patients with mycetomas may require 6 to 12 months of therapy; localized cutaneous nocardiosis usually is treated for 3 to 6 months. Therapy for 6 to 12 months is suggested for patients with serious infection. Therapy for 12 months is indicated for patients with central nervous system nocardiosis and for immunocompromised patients.[38] Patients with central nervous system disease should be monitored with serial neuroimaging studies. Patients with AIDS probably should be treated with suppressive therapy indefinitely.

Surgical drainage of abscesses is important because metastatic abscesses can appear in the face of adequate therapy until surgical drainage is achieved.[23] Select brain abscesses may respond to antimicrobial treatment without surgery.[40]

Despite specific therapy, the overall mortality rate is 25 to 40 percent.[50,51] Most reported cases involving dissemination to the central nervous system have been fatal.[50] Disseminated nocardiosis has a poor prognosis, with a mortality rate of greater than 85 percent in

immunocompromised hosts.[4] Factors associated with increased mortality rates in one reported patient series were treatment with corticosteroids or antineoplastic agents, underlying Cushing disease, disseminated disease involving two or more noncontiguous organs or the central nervous system, and the presence of symptoms for less than 3 weeks before initial evaluation.[50]

CHAPTER 100

Corynebacterium and Rhodococcus

Randall G. Fisher

The gram-positive rods encompass a vast number of species. They are widespread in the environment and are part of the normal flora of animals and humans. The focus of this chapter is on gram-positive bacilli seldom encountered as pathogens in healthy individuals. Many of these organisms show increasing prominence as causes of disease in immunocompromised patients.[13] Bacteria from the genera *Corynebacterium* (other than *Corynebacterium diphtheriae*) and *Rhodococcus* are discussed.

CORYNEBACTERIUM

The genus *Corynebacterium* comprises a wide number of organisms possessing little pathogenic potential, with some notable exceptions. The most infamous member of this genus, *C. diphtheriae* (see Chapter 90), is a cause of a potentially lethal pharyngeal infection with systemic manifestations. *Corynebacterium jeikeium* (formerly *Corynebacterium* group JK) can be a major nosocomial agent of bacteremia and endocarditis; other species commonly are associated with infections in animals and rarely cause invasive infection in humans.[83,119] For an exhaustive consideration of coryneform bacteria, the reader is referred to the review by Funke and colleagues.[50]

BACTERIOLOGY

Corynebacterium spp. derive their name from their club-like shape. Because of their resemblance to *C. diphtheriae*, they are included in the heterogeneous group of diphtheroids. Snapping division produces the angular and palisade arrangement of cells responsible for their characteristic gram-positive, "Chinese letters" microscopic appearance.[27] Organisms are facultatively anaerobic or aerobic and do not produce spores. They are nonmotile and catalase positive and contain mycolic acid in their cell walls. Clinically relevant species include *C. diphtheriae*,

C. jeikeium, *C. pseudotuberculosis*, *C. xerosis*, *C. amycolatum*, *C. pseudodiphtheriticum*, *C. minutissimum*, *C. striatum*, *C. ulcerans*, and *C. urealyticum*. Species can be differentiated according to biochemical tests and fermentation of sugars.[27,50,115]

EPIDEMIOLOGY

Corynebacterium spp. can be part of the normal skin and upper respiratory tract flora and commonly colonize hospitalized patients. Nosocomial acquisition of *C. jeikeium* has been characterized most completely. Thirty-five percent of hospitalized patients may be colonized with *C. jeikeium*, and the organism may be isolated at the time of admission.[52] The skin, groin, and rectum are common sites of recovery of organisms. Wounds and suppurative sites quickly become colonized.[52] Longer duration of hospitalization, receipt of broad-spectrum antimicrobial agents, and impaired skin integrity are risk factors for invasive infection. Hospital personnel caring for oncology patients have higher rates of hand colonization with pathogenic *Corynebacterium* spp. than do nurses caring for dermatology patients.[66] Transmission from patient to patient in the hospital environment can occur, and selective antibiotic pressure has been shown to augment colonization with *Corynebacterium* spp.[81,95,154] Outbreaks of bacteremic infection have been reported in hematology wards,[112,132] and DNA restriction fragment analysis and hybridization techniques have been used to document spread.[81,109]

PATHOPHYSIOLOGY

C. jeikeium and *C. urealyticum* are lipophilic, which may account for their ability to proliferate on skin that has a higher lipid content; organisms have been isolated from sebum-filled eccrine gland biopsy specimens in an adolescent with malignancy.[71] Breach of the integrity of the skin is an important risk factor for acquisition of local infection and bacteremia with *Corynebacterium*. Plastic intravascular catheters increase the risk for infection.[113] Certain isolates of *C. pseudotuberculosis* and *C. ulcerans* can express diphtheria-like toxins,[152] which may confer virulence.

Some *Corynebacterium* spp., notably *C. jeikeium* and *C. urealyticum*, commonly show resistance to penicillins, cephalosporins, aminoglycosides, erythromycin, and tetracycline.* Strains with a significant DNA relationship to the *C. jeikeium*–type strain show penicillin resistance.[114] Resistant organisms have been noted to have significantly thickened cell walls compared with susceptible strains, but the functional importance of this feature is unknown.[16]

CLINICAL MANIFESTATIONS

Systemic infections with *Corynebacterium* spp. generally are not clinically distinguishable from serious infections caused by other pathogens. Immunocompromised patients are at the highest risk for developing disease caused by *Corynebacterium*,[62,118] but infections also have been described in neonates and immunocompromised older children.[14,38,74] Risk factors include male gender, neutropenia, broad-spectrum antibiotic exposure, and prolonged hospital stay.[112,132] Catalase production may be responsible for the rare infection with non-JK *Corynebacterium* spp. in children with chronic granulomatous disease.[74] *Corynebacterium* spp. are responsible for approximately 9 percent of early-onset and 4 percent of late-onset prosthetic valve endocarditis.[151]

C. jeikeium is a pathogen of particular concern. In 1976, this agent first was described as a cause of serious infection in four patients, including an 11-year-old boy with a ventriculoatrial shunt.[62] The other three patients had hematologic malignancies and were neutropenic at the time of infection. Immunocompromised patients, particularly patients with leukemia, are vulnerable to bacteremia. These high-risk subjects may show a local inflammatory lesion at the site of infection or a disseminated, hemorrhagic, or necrotic papular exanthem.[105] Subcutaneous nodules also may be seen. *C. jeikeium* has been recovered from disseminated lesions in a 14-year-old boy with leukemia.[71] A literature review of 83 neutropenic patients (nearly all adults) with *C. jeikeium* sepsis found the following risk factors for development of infection: presence of a central venous catheter, being male, profound and prolonged neutropenia, and exposure to multiple antibiotics. Skin lesions were reported in 48 percent of patients and pulmonary infiltrates were found in 36 percent of patients. The overall case-fatality rate was 34 percent, but it was reduced to 5 percent in patients with recovery from neutropenia.[144]

Infections with *C. jeikeium* also have been reported after trauma, ventriculoperitoneal shunting procedures,[3,76] orthopedic procedures,[26] bone marrow aspiration,[38] and central venous catheter placement.[38] *C. jeikeium* now is recognized to be one of the most common causes of prosthetic valve endocarditis in adults.[102] Cutaneous findings of bacteremia so commonly observed in patients with cancer generally are absent in patients with endocarditis.[33] In a series of 38 patients with *C. jeikeium* endocarditis, 74 percent of patients had prosthetic valves. The mortality rate was 33 percent and was not altered by valve replacement surgery.[100] According to a newer study, cases of endocarditis caused by *C. jeikeium* are more likely to require valve replacement than are those caused by other *Corynebacterium* spp.[12] Exit-site infections in patients on continuous ambulatory peritoneal dialysis also may be caused by *Corynebacterium* spp.; in the largest series published to date, *C. striatum* caused almost twice as many of these infections as did *C. jeikeium*. Most infections are manageable without removal of the dialysis catheter.[123]

Although primarily a pathogen in farm animals, *C. pseudotuberculosis* can cause localized suppurative granulomatous lymphadenitis in humans[83,99]; almost all cases are associated with animal contact, particularly sheep and goats.[53] Presentation and histology may mimic the much more common cat-scratch disease, and Gram stain and culture are required to differentiate the two entities.[83]

*References 38, 52, 83, 95, 102, 115, 130.

Most cases have been reported from Australia.[107] The complete genome of an isolate taken from a 12-year-old girl with suppurative lymphadenitis has been sequenced.[142]

C. xerosis has been reported as a rare cause of endocarditis, arthritis, and ventriculoperitoneal shunt infection.[7,17] Most individuals with endocarditis have a prosthetic heart valve.[42,86] In one case an implantable cardioversion device became infected with the organism.[90] *C. xerosis* also can be a cause of eye infections in patients with superficial corneal foreign bodies; in one study of 101 patients, *C. xerosis* caused 3 of 15 culture-positive cases.[87] It also is an extremely rare cause of post-LASIK (laser-assisted in-situ keratomileusis) infectious keratitis.[37] Using chemical testing and molecular genetic investigation, Funke and colleagues[49] showed that many isolates tentatively identified as *C. xerosis* are actually *C. amycolatum*. *C. amycolatum* is much more likely to be multidrug-resistant than *C. xerosis*.[50] *C. amycolatum* is a comparatively common cause of bacteremia in children with cancer; of 12 cases of corynebacterial bacteremia reported from St. Jude Children's Research Hospital, 3 were caused by this species. In contrast to reports in adults, corynebacterial bacteremia in children usually started in the outpatient setting, happened in patients who were non-neutropenic, occurred relatively late in the course of cancer therapy, and had a relatively benign outcome.[1] In adults with cancer, *C. amycolatum* was often recovered from the upper urinary or lower respiratory tracts or found in surgical wounds or as an infection of ulcerating tumors.[93] A case of fatal sepsis in a premature neonate caused by *C. amycolatum* has been reported.[14]

C. pseudodiphtheriticum, a commensal of the oropharynx, can cause pneumonia, bronchitis, or tracheitis.[2,28,31] Lung disease usually occurs in the context of underlying cardiopulmonary pathology or immunocompromise.[60] Onset typically is acute, but fever may be noticeably absent.[88] One cystic fibrosis center in France reported that 10 children had exacerbations that appeared to be related to respiratory tract infection with *C. pseudodiphtheriticum;* matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry was used to identify the isolates.[15] At least 18 cases of *C. pseudodiphtheriticum* endocarditis, including three infections in children with congenital heart disease, have been reported.[101] Infection of allograft material is a common finding; native heart valves may be involved but usually in the context of preexisting lesions or intravenous drug abuse. In adults, endocarditis due to *C. pseudodiphtheriticum* has a predilection for men who have had a previous prosthetic valve replacement; infection with toxigenic strains appears to have a higher mortality rate.[12] Three cases of exudative pharyngitis with a pseudomembrane mimicking diphtheria, including one in a 4-year-old girl from Arkansas, have been reported to be caused by *C. pseudodiphtheriticum*.[70] In one case, a surface swab from a draining wound after arthroscopy was reported to harbor "normal skin flora" but joint fluid grew the same organism, which was finally identified as *C. pseudodiphtheriticum*. Treatment resulted in resolution of symptoms of septic arthritis.[75] Patients who are immunocompromised and have corneal epithelial defects can get severe eye infections with this organism.[82] Rarely, ulcerative skin lesions have been described due to *C. pseudodiphtheriticum*.[22]

C. minutissimum traditionally has been regarded as the cause of the mild cutaneous disease erythrasma, which is characterized by scaly, pruritic red-brown patches, usually occurring in the axilla or groin. Although *C. minutissimum* may play a role, erythrasma probably is a polymicrobial process.[50] *C. minutissimum* is recognized as a rare nosocomial infectious complication of malignancy and dialysis and has been implicated in a case of pyelonephritis in an 8-month-old infant with posterior urethral valves.[30] An adult who developed native-valve endocarditis caused by *C. minutissimum* has been reported.[6] A newer case report describes bacteremia and meningitis due to this organism in a patient with sickle-cell disease with an intravenously implanted right subclavian port.[32]

C. striatum has been recovered from purulent sputum of hospitalized patients and from infected central venous catheter sites.[125,148] It also is a cause of exit-site infections in patients on long-term ambulatory peritoneal dialysis.[123] It has been reported as a cause of fatal pulmonary infection and endocarditis.[81,92,119] *C. striatum* was responsible for a nosocomial outbreak among 14 patients over a 12-month period in a surgical intensive care unit. Endotracheal intubation for longer than 24 hours was the only risk factor found to predispose to infection.[19] A second intensive care unit outbreak was reported from Italy; in this series, one of the patients was a 16-year-old admitted for severe trauma that resulted in having a sepsis-like picture and three blood cultures positive for *C. striatum*. Despite therapy with teicoplanin and meropenem, the patient died.[68] *C. striatum* also has been reported as a cause of meningitis and ventriculoperitoneal shunt infections.[67,149] One case of septic arthritis that developed 20 days after a therapeutic knee aspiration has been reported.[124]

C. ulcerans derives its name from its association with ulcerative pharyngitis. Although it is more commonly a pathogen of nonhuman primates,[106] infection can occur in humans after contact with an animal or consumption of contaminated raw milk.[11,34] Toxigenic strains of *C. ulcerans* can produce a syndrome indistinguishable from that caused by toxigenic *C. diphtheriae*.[23,140] In the United Kingdom, domestic *C. ulcerans* is now a more common cause of diphtheria than *C. diphtheriae*.[147] Cases in the United States are decidedly rare; the case of an 80-year-old man in Idaho reported in 2010 was the first case in 5 years.[24] Skin lesions that exactly mimic cutaneous diphtheria, caused by diphtheria toxin–secreting strains of *C. ulcerans*, also have been reported.[146]

C. urealyticum (formerly *Corynebacterium* group D2) is a cause of alkaline-encrusted cystitis and pyelitis, primarily in the elderly.[44,130] A case series of four children with encrusted cystitis and pyelitis has been published. The mean age was 9 years (range, 4 to 13 years). Treatment was with prolonged antibiotics and endoscopic debulking. Cure was effected in three of the four patients; the other patient was a renal transplant recipient who lost the graft.[98] A prospective study of renal transplant recipients suggested that it is likely an underdiagnosed cause of obstructive uropathy in this group of patients; risk factors for infection were receipt of antibiotics in the previous

month, nephrostomy, and skin colonization with the organism.[85] Routine urine culture may miss the organism; it may grow with prolonged incubation of sheep's blood agar.[127] It is associated less commonly with infection at other sites and with bacteremia.[129] An 8-year-old boy with chemotherapy-induced neutropenia and a necrotic soft tissue infection of the scrotum caused by *C. urealyticum* has been reported.[120] Cure of bacteremia in a patient with obstruction due to prostate cancer was not effected until his percutaneous nephrostomy tube was removed.[25]

DIAGNOSIS

Diagnosis of *Corynebacterium* infection is based on isolation of the organism from clinical material. This organism commonly is accompanied by other pathogens. Similar to *Mycobacterium* and *Nocardia* spp., *Corynebacterium* organisms have mycolic acids in their cell wall. The chains are shorter, however, and the organisms are not acid fast. *Corynebacterium* spp. may be difficult to distinguish from some *Rhodococcus* spp.[27] Colonies of *C. jeikeium* may show a metallic sheen when grown on agar.[62] Growth of *C. jeikeium* is enhanced by the addition of lipids to the medium. Most *Corynebacterium* spp. can be differentiated quickly from each other by sugar fermentation, hydrolysis of urea, and reduction of nitrate.[139] Selective media containing kanamycin or trimethoprim-sulfamethoxazole have been useful in the recovery of multidrug-resistant strains of *Corynebacterium*.[61] The API Coryne system version 2.0 correctly identified 162 of 178 (91%) isolates in one study.[5] Polymerase chain reaction (PCR) testing and MALDI-TOF spectrometry are quite accurate for specific identification at the species level, but these tests are not yet widely available. Erythrasma usually is diagnosed by the typical coral red fluorescence under Wood lamp examination.

TREATMENT

Empirical therapy for infection must account for the frequency of infection with *C. jeikeium*, which often is multiresistant to antibiotics but is susceptible to vancomycin.[50] In some series of immunocompromised patients, this organism is the most common *Corynebacterium* spp. encountered.[131,150] Vancomycin is recommended for empirical therapy for suspected *Corynebacterium* infection until susceptibilities are known. Treatment can be changed to a penicillin or cephalosporin, if appropriate. In vitro, *C. jeikeium* is sensitive to linezolid,[55] and most strains also are sensitive to quinupristin-dalfopristin[121] and daptomycin.[54] A majority of strains is also sensitive to tigecycline, but experience with the antibiotic in childhood is sparse.[45] Linezolid is bacteriostatic against all species of *Corynebacterium*, and in vitro its activity is slower against *C. jeikeium* than it is against *C. striatum* and *C. amycolatum*.[55]

Two-drug therapy generally is recommended for treatment of *Corynebacterium* endocarditis; for gentamicin-susceptible strains, penicillin-gentamicin combinations have been shown to be synergistic, regardless of whether the strains are susceptible to penicillin.[102] Rarely, resistance to vancomycin is encountered. A woman with prosthetic valve endocarditis caused by a vancomycin-resistant *Corynebacterium* spp. was treated successfully with imipenem and ciprofloxacin.[10] Removal of infectious sources, such as central nervous system shunts and central venous catheters, may be required for cure. Scrupulous attention given to skin hygiene may reduce colonization of hospital personnel and the incidence of patient-to-patient transmission of pathogenic strains.[40,112] Management of toxigenic *C. ulcerans* infection is identical to that for infection caused by toxigenic *C. diphtheriae*, including the use of antitoxin.[140] Erythrasma usually responds to treatment with a macrolide.

RHODOCOCCUS

The genus *Rhodococcus* contains at least 15 species, of which *Rhodococcus equi* is the most clinically relevant to humans. Infections with other species are rare. Suppurative keratitis caused by *Rhodococcus ruber* after penetrating trauma has been described.[78] This organism derives its name from its role as a cause of pyogranulomatous pneumonia in young horses.[110] It has assumed a prominent role as a cause of human pulmonary disease in immunocompromised patients, particularly in patients with acquired immunodeficiency syndrome (AIDS).[43,63,125] For a comprehensive discussion of this organism, the reader is referred to the review by Cornish and Washington.[29]

BACTERIOLOGY

R. equi is a catalase-positive, urease-positive, oxidase-negative, gram-positive rod. The organism assumes a more coccoid morphology in solid media and a more bacillary form in liquid media. Its cell wall contains mycolic acid, rendering it acid fast when grown on Lowenstein-Jensen media and stained with Kinyoun stain.[56]

EPIDEMIOLOGY

R. equi is a soil organism, and its growth is enriched by the manure of herbivores. Despite the common occurrence of this pathogen as a cause of veterinary infections, exposure to animals apparently is not necessary for human infection to occur[110]; most reported human patients have not had farm or animal exposure.[63] Hospital outbreaks of infection associated with patient-to-patient transmission have not been reported. In a retrospective analysis of 24 cases of *R. equi* infection, however, six patients had shared

a hospital room with a patient with *R. equi* pneumonia, raising the possibility of nosocomial transmission.[8] Most patients diagnosed with *Rhodococcus* infection are immunocompromised; AIDS is the most common underlying diagnosis, but infection also has been reported in transplant patients[9] and rarely in patients believed to be immunocompetent.[143] In one case, infective endocarditis with severe complications including subarachnoid hemorrhage and subdural hematoma was reported in a patient with a normal immune workup.[94] On the other hand, a chronic, nonhealing ulcerative lesion caused by *R. equi* in a man believed to be immunocompetent led to a diagnostic workup that proved the cause to be a CD8 deficit.[36]

Chemotherapeutic agents such as fludarabine, which causes prolonged CD4 lymphocytopenia, can predispose to *R. equi* infection.[51] Receipt of high-dose corticosteroids[116] and alemtuzumab (an anti-CD52 monoclonal antibody) have also been reported as antecedents of infection.[97]

PATHOPHYSIOLOGY

The prominence of pulmonary infection suggests that the respiratory tract is a common portal of entry. After gaining access to the lower respiratory tract, organisms are taken up by alveolar macrophages; Mac-1 macrophage receptors and complement are required for binding.[64] The appearance of pyogranulomatous lesions is consistent with the role of *R. equi* as an intracellular parasite containing mycolic acid, a possible virulence factor in the cell wall.[57,111] Surface 15- and 17-kDa antigens expressed by an 85-kb plasmid seem to confer virulence in mice and foals,[134] and virulent strains seem to have an increased capacity for intracellular survival in macrophages.[65]

Most *R. equi* isolates from patients with AIDS express either the 15- to 17-kDa antigens or a 20-kDa antigen that seems to confer intermediate virulence. Most isolates from patients without AIDS express none of these antigens, however.[135] Other factors may play a role in promoting *Rhodococcus* disease in humans.[136] Death of parasitized macrophages may release enzymes, which contribute further to tissue damage. $CD4^+$ lymphocytes are essential for pulmonary clearance of *R. equi* in a mouse model,[73] which may help to explain the high risk for infection associated with cellular immunodeficiency.

CLINICAL MANIFESTATIONS

Infection typically manifests as a subacute pneumonia developing over several weeks. Symptoms such as cough and fever are common, but progression of disease may be silent. Although most infections currently occur in patients with AIDS, malignancy and transplantation also pose risks. Pulmonary infection in children with leukemia has been described.[4,96] Infection may be accompanied by other pathogens, particularly in patients with AIDS.

Pulmonary infection often is pleura based and associated with cavitation.[63] Empyema may occur as a complication. Computed tomography most frequently reveals pneumonia with cavitation, but other patterns, including "ground-glass" opacities, peribronchial nodules, and centrilobular nodules, may be seen.[89] Lung tissue showing malakoplakia, an unusual-appearing granulomatous inflammation with aggregates of histiocytes that contain concentrically layered basophilic inclusions, should raise suspicion of the presence of *R. equi* infection.[21,58,122]

Extrapulmonary disease is seen at diagnosis in 7 percent of patients with pneumonia.[145] Manifestations of infection include otitis/mastoiditis,[4,69,84] abscesses,[46] osteomyelitis,[18,47,104] meningitis,[35,126] pericarditis,[80] lymphadenitis,[80] and endophthalmitis.[41] The organism has been grown from a biopsy of a granulomatous skin lesion in an immunocompetent 7-year-old girl.[91] *R. equi* also has been reported as a cause of peritonitis in patients receiving long-term peritoneal dialysis.[20,137] A case report of ventriculitis in a premature infant with a ventriculoperitoneal shunt has been reported.[133]

DIAGNOSIS

Diagnosis relies on isolation of *Rhodococcus* from clinical material. Although sputum specimens may be positive, bronchoalveolar lavage or lung biopsy may be required. Blood cultures may be positive in half or more of patients with AIDS and with focal pneumonic disease.[141] The physician should be alert to the possible coexistence of *R. equi* with other pathogens. In the laboratory, confusing this organism with *Corynebacterium*, acid-fast organisms, and other gram-positive coccobacilli has been shown to delay establishment of the diagnosis.[39] Positive findings on Gram stain and Kinyoun stain should be interpreted in the context of clinical information.[125] Organisms appear salmon-pink when grown on blood agar and orange on Lowenstein-Jensen medium.[13] Differentiating from acid-fast bacteria on smear sometimes can be difficult. Combined use of a siderophore detection medium, ethylene glycol degradation, and β-galactosidase activity may help differentiate *Rhodococcus* from *Nocardia* and rapid-growing mycobacteria.[48] DNA restriction fragment analysis and ribotyping show promise in aiding the identification and tracking of *Rhodococcus* spp.[79] An *R. equi*–specific PCR assay has been used to confirm infection in some cases in which identification was difficult.[1]

Differentiation of *R. equi* from other species of the genus *Rhodococcus* can be difficult and may frequently be incorrect; 16S rRNA genome sequencing analysis sometimes identifies a different species of *Rhodococcus* from specimens originally signed out as *R. equi*.[59] Also, organisms of the new genus *Dietzia* are often misidentified as *R. equi*.[77] In one study, only 7 of 15 clinical specimens originally called *R. equi* by the microbiology laboratory were actually *Rhodococcus* isolates; the 8 others were all members of the genus *Dietzia*.[108]

TREATMENT

Clinical isolates commonly are resistant to penicillins and cephalosporins. Even if susceptible in vitro, β-lactam

antibiotics should be avoided because of rapid development of resistance.[72] Erythromycin, clarithromycin, azithromycin, clindamycin, rifampin, aminoglycosides, vancomycin, fluoroquinolones, and imipenem are active against *R. equi*.[103] Moxifloxacin is more active in vitro than is either ciprofloxacin or levofloxacin.[117] Synergy has been shown with various combinations of these agents. Including rifampin or erythromycin in a two-drug combination has been recommended because of penetrance of macrophages.[13,128] Combinations of antibiotics that included vancomycin were found to be most effective in clearing infection in a mouse model.[103] Cure rates in adults with lung infection are approximately 60 percent when antibiotic therapy alone is employed but may reach 75 percent when combined with surgical resection of infected pulmonary tissue.[63] Surgery has not been shown to increase survival rates, however.[8]

Pediatric patients generally have fared better than adults, but most reported cases in children have been in non-AIDS patients.[13] Relapse is a common occurrence, but the optimal duration of therapy to prevent relapse is unknown. For patients with AIDS, some authors recommend a minimum of 2 months of therapy followed by long-term suppressive therapy.[72] Relapse has been reported to occur at extrapulmonary sites in 13 percent of immunocompromised patients,[145] often without reappearance of pulmonary disease. Treatment of *R. equi* peritonitis in patients receiving peritoneal dialysis has been reported to be successful with intraperitoneal imipenem or vancomycin for 14 days.[20,138] Removal of the peritoneal dialysis catheter may be required for cure.

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

SUBSECTION 4 *GRAM-NEGATIVE BACILLI*

CHAPTER 101

CITROBACTER

Randall G. Fisher

Citrobacter, a genus of enteric gram-negative rods closely related to *Salmonella*, has been associated increasingly with human disease. Although *Citrobacter* strains usually are not considered normal inhabitants of the intestinal tract of humans and animals,[56,92] a study using 16S rDNA polymerase chain reaction (PCR) showed that normal newborns are colonized with these organisms by day 6 of life.[66] They have been associated with urinary tract infections,* osteomyelitis,[52] diarrhea,[18,30,95] and invasive disease in the immunocompromised host.[37,41,52,56] As detailed in a review by Doran,[16] *Citrobacter* commonly is associated with sepsis, meningitis, and brain abscess in neonates.

BACTERIOLOGY

In 1931, Werkman and Gillen[92] proposed the generic term *Citrobacter* for citrate-positive coli-aerogenes intermediates isolated from stool. This genus now includes 11 species, of which the most commonly identified are *Citrobacter freundii*, *Citrobacter koseri* (formerly *Citrobacter diversus*), and *Citrobacter farmeri* (formerly *Citrobacter amalonaticus*).[7] *Citrobacter* are straight, facultatively anaerobic bacilli possessing peritrichous flagellae that confer motility. In addition to using citrate, these organisms hydrolyze urea and ferment glucose, with production of gas.[79] They grow on ordinary media as gray, opaque, round colonies that produce a strong, fetid odor. In contrast to *Salmonella*, *Citrobacter* grows in the presence of potassium cyanide. Indole-negative strains that produce hydrogen sulfide are classified as *C. freundii*. Indole-positive, hydrogen sulfide–negative strains are differentiated by their ability to ferment malonate; *C. koseri* ferments malonate, whereas *C. farmeri* does not.[2] Antigenic schemata have been developed to classify the O somatic antigens of *Citrobacter*[25,29,95]; these antigens show cross reactivity with O antigens of other Enterobacteriaceae.

EPIDEMIOLOGY

Meningitis caused by *Citrobacter* was reported first in 1960, with two cases of *C. freundii*.[34] In the decade from 1970 to 1979, 69 cases of *Citrobacter* meningitis were reported,[26] and 4 percent of neonatal meningitis cases reported in the First Neonatal Meningitis Cooperative Study Group were caused by *Citrobacter*.[61] *C. koseri* is the species usually isolated with meningitis; central nervous system infection caused by *C. freundii* occurs less commonly.[16,26] Most cases in the United States are reported from southern states; biotype d or serotypes O2 and O1[26] are the most common isolates of *C. koseri* encountered.

Most cases of neonatal meningitis caused by this organism have been sporadic. The source of sporadic cases usually is unknown, but nine cases clearly have been documented to be vertically transmitted from mother to infant.[16] In addition, several well-documented nosocomial outbreaks of infection have been reported.* The source usually is the gastrointestinal tract or hands of nursery staff. One cluster was associated with contaminated formula.[86] When *Citrobacter* is introduced into the neonatal nursery, colonization may exceed 79 percent.[25] Parry and associates[67] described a nursery outbreak in which 11 of 128 infants were colonized with *C. koseri* over an observation period of 3 months; 2 of the colonized infants developed meningitis. Additional colonization of neonates seemed to be eliminated by removal of a nurse with persistent hand carriage of the organism.

In another outbreak,[95] introduction of *C. koseri* into the nursery was linked to an infant admitted with meningitis. Thirty-one percent of infants in the nursery subsequent to the index case were found to be colonized with *C. koseri* of the same serotype and biotype. A second infant from this study developed meningitis with the organism during the observation period. Umbilical colonization of infants in this cluster was more common than was rectal colonization, but rectal colonization was more persistent, lasting 4 months. Two nurses were found to

*References 6, 23, 41, 49, 52, 56.

*References 19, 23, 25, 51, 67, 74, 95.

have hand colonization with the organism, and the reintroduction of these bacteria into the nursery was linked to a pregnant nurse who had perineal cultures at delivery yielding the epidemic strain. She was implicated in the colonization of her own infant and three other neonates. Corresponding culture data from a reference hospital revealed an overall neonatal colonization rate with *Citrobacter* of 1 to 10 percent over a 5-year period, with no invasive disease.

Although *Citrobacter* has been isolated increasingly from debilitated adult patients,[93] particularly as a urinary tract,[41,52,56] soft tissue,[17,52,56] and bone[56] pathogen, *Citrobacter* infection in children is unusual after the first 2 months of life. One case of meningitis was reported in a teenager who lacked apparent risk factors or immunodeficiency.[73] In older children, *Citrobacter* spp. are more likely to cause opportunistic infection in an immunocompromised host or, occasionally, urinary tract infection. One study showed *Citrobacter* spp. to be responsible for 37 (1.4%) urinary tract infections in children over a 3-year period.[21] One quarter of infections were nosocomially acquired, and one third occurred in children with urinary tract abnormalities. A more recent study from Kosovo of 299 children with urinary tract infections found that *Citrobacter* spp. caused 5.4 percent of cases, making it the fourth most common cause.[81]

PATHOPHYSIOLOGY

Citrobacter infrequently colonizes the intestinal tract and perineum of humans.[41] Vertical transmission of strains shown to be identical by DNA typing shows that the newborn can acquire colonization at the time of passage through the birth canal of a colonized mother.[35,65] Onset of disease beyond the first week of life is related commonly to colonization of the infant in the nursery. As with other types of gram-negative neonatal meningitis, central nervous system infection results from bacteremia in a colonized infant, leading to seeding of the meninges.

The basis for the particular invasiveness of *Citrobacter* in the neonate and its propensity to cause multiple brain abscesses are largely unexplained. *Citrobacter* spp. possess the ability to invade, transcytose, and multiply within human brain microvascular endothelial cells in vitro.[3] Additionally, in the neonatal rat model, after being taken up into macrophages, *C. koseri* is able to survive phagolysosomal fusion and replicate therein.[87] Many strains of *C. koseri* seem to be able to produce brain pathologic processes in the mouse, but the degree of damage seems to be related to virulence of the strain and the age of the mouse.[47,80] Differences in strains, related to the presence of an outer-membrane protein with a molecular weight of 32,000, have been associated with differences in brain histopathology in one infant rat model of *C. koseri* meningitis.[46] Strains isolated from cerebrospinal fluid of infants with meningitis more commonly possess this outer-membrane protein than do strains isolated from other body sites.[47] In the mouse model, early proinflammatory mediator release was dependent on MyD88 (a signaling adapter of Toll-like receptor 4 [TL4]). MyDD88 knockout mice had enhanced mortality and elevated bacterial burdens versus wild-type mice.[53] In vitro, microglial cells respond with inflammation via TL4 and MyD88.[54]

In an immunocompromised patient, broad use of antimicrobial agents may produce selective pressure, leading to increased colonization with *Citrobacter*. Increased bacterial density combined with a blunted immune response may result in invasive disease. Some strains of *C. freundii* have been shown to produce Shiga toxins (verotoxins) nearly identical to those produced by enterohemorrhagic strains of *Escherichia coli*.[77] At least one outbreak of gastroenteritis and the hemolytic-uremic syndrome caused by Shiga-toxin–producing *C. freundii* has been reported.[89]

Citrobacter spp. contain type 3 fimbriae, which are vital to the production of biofilms.[64] The formation of biofilms in *Citrobacter* isolates is important in the pathogenesis of catheter-associated urinary tract infections.[64]

CLINICAL MANIFESTATIONS

Citrobacter, similar to other neonatal pathogens, can cause early-onset and late-onset infection. In a review of 74 cases of neonatal meningitis caused by these bacteria, the mean age of onset reported for early disease was 7 days; 85 percent of patients were included in this group.[26] Fifteen percent of cases occurred after 3 weeks of age. Twenty-three (31%) of 74 patients were younger than 36 weeks of gestational age at birth, suggesting that preterm infants are at increased risk for acquisition of *Citrobacter* infection. Prematurity is even more common (71%) in cases that are proved to be vertically acquired.[16]

Clinical signs and symptoms are typical of neonatal sepsis. Fever, lethargy, poor feeding, vomiting, irritability, bulging fontanelle, seizures, and jaundice are common presenting features. Umbilical infection and surgical manipulation of colonized umbilical stumps occasionally have preceded development of bacteremia and meningitis.[67] The white blood cell count may show leukocytosis or leukopenia. Cerebrospinal fluid findings are consistent with those of most types of neonatal bacterial meningitis and usually show polymorphonuclear cell elevation, elevated protein, and depressed glucose; gram-negative rods may be seen on smear. Although growing the organism in culture normally is not difficult, in one reported case standard cultures were negative, but the organism was recovered by direct inoculation of cerebrospinal fluid into a BACTEC blood culture bottle.[14] Of *Citrobacter* meningitis cases in which the results of blood cultures are reported, 80 percent document concurrent bacteremia.[16]

Citrobacter is a particularly devastating cause of neonatal meningitis. The most common *Citrobacter* spp. causing neonatal meningitis is *C. koseri*, which accounts for more than 80 percent of the cases.[16] Central nervous system infection with this organism produces multiple brain abscesses with unusually high frequency.[26,32,42,47,50] In the extensive reviews by Graham and Band[26] and by Doran,[16] three quarters of *Citrobacter* meningitis cases resulted in intracerebral abscesses. By comparison, the incidence of abscess formation in non-*Citrobacter*

gram-negative meningitis is reported to be as low as 10 percent.[26] The case-fatality rate for *Citrobacter* meningitis is approximately 30 percent, and at least three quarters of surviving infants have neurologic sequelae, such as mental retardation, hemiparesis, seizures, and developmental delay.[16]

The presence of brain abscess seems to contribute significantly to morbidity and mortality.[15,25,26] For unknown reasons, neonates with vertically acquired *Citrobacter* meningitis seem to be less likely to develop intracerebral abscesses.[16] At least three cases in which diffuse pneumocephalus developed in association with *Citrobacter* meningitis have been reported; in one, gas was noted to accumulate within the brain and in the anterior chamber of the eye, a condition known as *pneumatosis oculi*.[1,72] Rarely, *Citrobacter* infection in the neonatal period may lead to focal infection not involving the central nervous system. A case of septic arthritis and osteomyelitis of the shoulder in a 3-week-old infant has been reported.[36]

In adults, *Citrobacter* is isolated most commonly from the urinary tract.[41,52,56] In earlier studies, 5 to 12 percent of bacterial isolates from urinary tract infections in adult patients were *Citrobacter*.[18,94] More recently, in a health maintenance organization, *Citrobacter* spp. accounted for only 0.8 percent of 4342 isolates from women with acute uncomplicated cystitis.[31] *Citrobacter* spp. are a similarly uncommon cause of urinary tract infection in children.[21] Sputum is the second most common clinical specimen to yield *Citrobacter* in adults[41]; lung abscess,[22] pneumonia,[52,56] bronchitis,[37] and septic arthritis[52] have been reported. *Citrobacter* is an occasional cause of bacteremia in hospitalized patients, accounting for approximately 0.5 percent of blood culture isolates.[70,78] In one series, all 45 patients had at least one underlying disease, with malignancies (particularly intra-abdominal tumors) and hepatobiliary stones being the most frequent coexisting conditions.[78] Polymicrobial bacteremia occurred in one third of patients. The case-fatality rate was 18 percent. In a series of 6 bacteremic patients who had *Citrobacter* species other than *freundii* or *koseri*, 5 of the 6 had associated intra-abdominal infection; cancer and cirrhosis were the most common underlying diseases.[48]

Gastrointestinal disease occasionally has been attributed to *Citrobacter*, but frequent isolation of this agent from normal stools often renders this diagnosis equivocal. This genus was implicated first in an outbreak of mild gastroenteritis by Barnes and Cherry[5] in 1946, and an outbreak of watery diarrhea in a Virginia infant care unit included two infants in whom isolates of enterotoxin-liberating *Citrobacter* were obtained from the stool.[30] Some studies have found higher incidences of *Citrobacter* isolation from the stool of patients with enterocolitis syndrome than from stools of control patients.[95] Shiga-toxin (verotoxin)-producing *C. freundii* isolated from organically grown parsley was associated with an outbreak of diarrhea and hemolytic-uremic syndrome in a daycare setting.[89] *C. freundii* has been found as a cause of appendicitis in a healthy adult,[52] peritonitis in adults with liver disease or pancreatitis,[52] neutropenic colitis after chemotherapy for breast cancer,[13] and meningitis in adults as a complication of neurosurgery.[85] A case of Meleney gangrene occurring after cesarean section delivery has been reported.[84]

A patient with diabetes developed necrotizing fasciitis caused by *C. freundii* associated with injury from a fish fin.[12] Bone and soft tissue infections occur[8,27,82]; 3 percent of *Citrobacter* pathogens were isolated from joint or bone in one adult series.[52] One 53-year-old man developed infection 3 weeks after total hip arthroplasty, a condition normally expected to be caused by *S. aureus*.[43] Eye infections, including keratitis,[24] traumatic endophthalmitis,[9] and endogenous endophthalmitis[11] have been reported. A case of *C. freundii* pharyngitis complicated by retropharyngeal abscess and mediastinitis was cured by minimally invasive surgery and intravenous antibiotics.[88]

DIAGNOSIS

Biochemical characteristics of *C. koseri* include lack of hydrogen sulfide production on triple-sugar iron agar, negative Voges-Proskauer reaction, use of citrate, motility, production of indole, decarboxylation of ornithine but not lysine, and production of acid from adonitol.[2] Identification of this organism as a pathogen in a nursery setting should heighten suspicion of its possible role in subsequent neonatal infections. *C. freundii* is indole-negative and hydrogen sulfide–positive, which differentiates it from *C. koseri*. *C. farmeri* differs from *C. koseri* because of the former's inability to ferment malonate. *C. freundii* and *C. farmeri* account for a significant portion of disease caused by *Citrobacter* in immunocompromised individuals and should be suspected particularly in this group of patients.[37] In some cases, *C. freundii* can be misidentified as *Cronobacter* spp. by commercial systems.[20]

Infants with invasive *Citrobacter* disease present in a similar fashion to infants with sepsis and meningitis of other causes. Such infants should undergo a thorough evaluation, including blood and urine culture and cerebrospinal fluid studies. Brain imaging studies should be done when the diagnosis is established. Computed tomography is the most common test used, although ultrasound often is more feasible for an unstable neonate and may be nearly as sensitive in detecting abscesses.[50,62,96] Serial imaging studies should be done because abscesses may develop during the first few weeks of illness. In cases in which the cerebrospinal fluid cultures are negative because of prior antimicrobial therapy, surgical aspiration of abscesses sometimes enables identification of the organism.

TREATMENT

Most *C. koseri* organisms are resistant to ampicillin (97% in one series)[52] and sensitive to aminoglycosides and third-generation cephalosporins.[16] A 4-year experience with neonatal septicemia caused by *C. koseri* has been described, however, in which all of 13 isolates were resistant to gentamicin but susceptible to third-generation cephalosporins.[19] The resistance patterns of *C. freundii* were reported in a national surveillance study of nosocomial bloodstream infections.[70] Of the 23 *C. freundii*

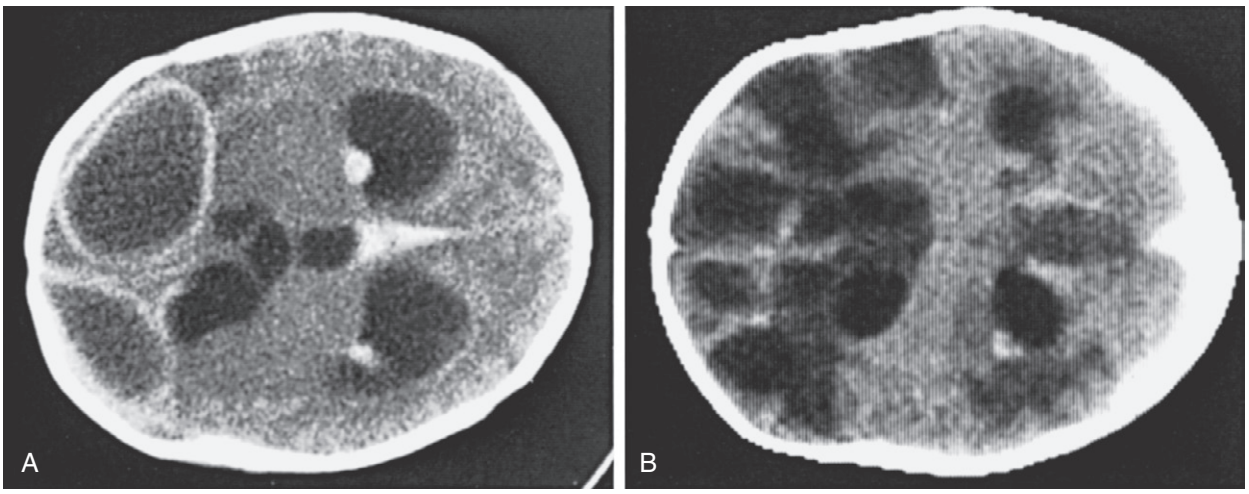

FIGURE 101-1 ■ Computed tomography scans showing progressive abscess formation and encephalomalacia in an infant at 3 weeks of age **(A)** and 6 weeks of age **(B),** despite bacteriologic "cure" of *Citrobacter* meningitis.

isolates tested, resistance to piperacillin, piperacillin/tazobactam, ceftriaxone, and ceftazidime was a common (39% to 48%) finding. Isolates generally were susceptible to the aminoglycosides and ciprofloxacin (91% to 96%), and all *C. freundii* tested were susceptible to cefepime and imipenem.

Some *Citrobacter* isolates contain chromosomally mediated group I β-lactamases. These bacteria possess a gene that, when triggered by exposure to cephalosporins or by spontaneous mutation, produces a cephalosporinase capable of inactivating cephalosporins.[38] Clinically, it manifests as treatment failure and emergence of drug resistance to various cephalosporins despite initial susceptibility.[57] In one study, the presence of group I β-lactamases was much more common with *C. freundii* (9/22 isolates) than with *C. koseri* (0/7 isolates).[38] Resistance was associated with previous receipt of an extended-spectrum, β-lactam antibiotic. Reliable estimates of the percentage of *Citrobacter* strains that contain the chromosomal resistance gene are difficult to obtain because most studies lump *Citrobacter*, *Enterobacter*, and *Serratia* isolates together. In one Korean study, of 152 *Enterobacter/Citrobacter/Serratia* isolates, 45 (30%) were derepressed AmpC mutants.[66] In an in vitro study, AmpC production was inducible in 8/9 clinical isolates of *C. freundii* and in 1/3 isolates of *C. koseri*. AmpC synthesis was stably derepressed in 1/9 *C. freundii* isolates.[17] Cefepime seems to be less likely to induce production of these β-lactamases and more resistant to hydrolysis by them,[76] although a highly cefepime-resistant strain has been described.[4] Of 3030 ceftazidime-resistant Enterobacteriaceae in a U.S. study, 99 percent retained susceptibility to imipenem and 96.7 percent of ceftazidime-resistant *Citrobacter* isolates were susceptible to cefepime.[71] Many different types of β-lactamases, including a novel TEM-type (TEM-134),[68] the class A β-lactamase CKO,[69] and a VIM-1 metallo-β-lactamase, have been described in various isolates of *Citrobacter*.[91] More recently, carbapenem resistance resulting from *Klebsiella pneumoniae* carbapenemase-2 (KPC-2) has been described.[10,58] Quinolone resistance via *qnr* genes has also been found in *C. koseri*[40]; in one study from Korea, 29 percent of *C. freundii* isolates were quinolone resistant. Most of these had *qnrB* genes.[39] Extensively resistant isolates are more likely to be sensitive to colistin[55] and polymyxin B[97] than to tigecycline.

Treatment of *Citrobacter* meningitis often requires a multidisciplinary effort involving the neurosurgeon and the pediatrician. Although cerebral abscesses usually are aspirated or drained surgically, some patients are treated with antibiotics alone and neither approach is clearly shown to be superior. When abscesses are inaccessible or small and not progressive, conservative management may be considered.[16] Ventriculostomy and craniectomy with open drainage of abscesses have been required in some children to effect bacteriologic cure, and placement of a shunt for hydrocephalus often is required.

Generally, antibiotic therapy for gram-negative neonatal meningitis has proved disappointing (see Chapter 66).[59,60] No evidence supports one combination of antibiotics over another in the treatment of *Citrobacter* meningitis. Usually a third-generation or fourth-generation cephalosporin or a carbapenem (usually meropenem) is used in combination with an aminoglycoside initially.[16] Chloramphenicol,[15,25,33] imipenem-cilastatin,[18,33] and trimethoprim-sulfamethoxazole[28] also have been used successfully.

Poor meningeal penetration of aminoglycosides in addition to the presence of intracranial abscesses render antibiotic therapy for *Citrobacter* meningitis especially difficult. The ability of this organism to persist in the brain is shown by its recovery 4 years after neonatal infection.[18] Cranial computed tomography usually is used for evaluation of complications such as hydrocephalus and multicystic encephalomalacia (Fig. 101-1). Administration of antibiotics intrathecally or directly into abscess cavities has been tried but has not been shown convincingly to be beneficial.* In a randomized controlled trial, intraventricular administration of gentamicin in the treatment of neonates with gram-negative meningitis was associated with a poorer outcome.[61]

*References 28, 29, 32, 45, 51, 63, 75, 83, 90.

Neonates with gram-negative meningitis should undergo repeat lumbar puncture approximately 72 hours after beginning therapy to document sterilization of cerebrospinal fluid. Duration of therapy with intravenous antibiotics generally is a minimum of 21 days for gram-negative neonatal meningitis. For cases complicated by intracranial abscesses, prolonged therapy (usually 4 to 6 weeks after sterilization of cerebrospinal fluid) is indicated.[16,44]

Scrupulous attention given to preventive infection control practices has been recommended to stem nursery outbreaks.[25,67,95] These prophylactic measures include care of skin and the umbilical cord, elimination of crowding with isolation of infected infants and carriers, and good hand washing practices. Exclusion of colonized personnel and temporary closing of the nursery have been followed by a reduction in neonatal *C. koseri* colonization. Although cohorting of colonized infants is a reasonable practice, multiple sources of introduction of *Citrobacter* may limit the efficacy of this approach in some outbreaks.[23]

Treatment of *Citrobacter* infection beyond the neonatal period requires choice of an appropriate antibiotic, with drainage of abscesses and appropriate débridement of wounds. Therapy should be guided by antimicrobial susceptibility testing. Outcome depends largely on the preceding debility of the host and location of the infection. Significant mortality is associated with immunocompromised patients with septicemia or pulmonary disease.[37,41,52,56,78]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 102

ENTEROBACTER

Laura A. Sass • Randall G. Fisher

Enterobacter is a genus of Enterobacteriaceae that is an increasingly frequent cause of health care–associated pediatric infection. *Enterobacter* can cause infection of postsurgical wounds, meningitis, and infection of the gastrointestinal, urinary, and respiratory tracts. Development of resistance to antibiotics commonly used for treatment of infection is an increasingly common challenge. For a more detailed overview of *Enterobacter* spp., the reader is referred to the review by Sanders and Sanders.[170]

BACTERIOLOGY

Enterobacter spp. are named for their enteric recovery as gram-negative bacteria.[165] They commonly are found in soil, water, and sewage. *Enterobacter* spp. also cause botanical disease. These organisms are facultatively anaerobic and motile by peritrichous flagella, with the exception of *Enterobacter asburiae*. Most species yield positive results on malonate, citrate, sucrose fermentation, and Voges-Proskauer tests. *Enterobacter sakazakii* is distinguishable from the other species by its yellow-pigmented colonies; it has recently been renamed *Cronobacter sakazakii*.[86] Taxonomic studies have led to several classifications of species contained in this genus. With the reclassification of *Enterobacter agglomerans* as *Pantoea agglomerans* (see Chapter 114), *Enterobacter cloacae* and *Enterobacter aerogenes* are the most common species recovered from clinical material.*

Additional species in the *Enterobacter* genus rarely recovered from human infections include *Enterobacter amnigenus*, *Enterobacter asburiae*, *Enterobacter gergoviae*, *Enterobacter cancerogenus* (formerly *Enterobacter taylorae*), *Enterobacter kobei* (formerly National Institutes of Health group 21),[102] *E. cloacae* subsp. dissolvens (formerly *Enterobacter dissolvens*), *Enterobacter nimipressuralis*, and *Enterobacter hormaechei*.† NIH group 42 strains now have become *Enterobacter cowanii*.[85] *Enterobacter intermedius* now has been reclassified to *Kluyvera intermedia* (formerly *Kluyvera cochleae*).[148] *Enterobacter ludwigii* is another new species isolated from clinical specimens that is closely related to the *E. cloacae* complex.[83]

EPIDEMIOLOGY

Enterobacter is encountered most commonly as a hospital-acquired pathogen in patients with chronic illness.‡ A surveillance study at 50 American medical centers showed *Enterobacter* as the eighth most common cause of health care–associated bloodstream infections, accounting for 230/4725 (5%) isolates.[155] Of these, 71 percent were *E. cloacae*, 23 percent were *E. aerogenes*, and 6 percent were other species of *Enterobacter*. *Enterobacter* infections are particularly common in intensive care units (ICUs).[129] A report from the Centers for Disease Control and Prevention (CDC) describing the epidemiology of health care–associated infections in 61 pediatric ICUs in the United States revealed that *Enterobacter* spp. were isolated with increasing frequency from patients with pneumonia and were the most common gram-negative isolates from bloodstream infections.[88] The frequency of *Enterobacter* spp. increased from 7 to 12 percent of reported pathogens over a 6-year period. *Enterobacter* spp. also were found to be second only to *Pseudomonas aeruginosa* in prevalence in health care–associated sinusitis.[166]

In other CDC surveys focusing on data from the National Healthcare Safety Network (NHSN), *Enterobacter* was one of the five pathogens most commonly encountered in ICUs and accounted for 5.0 to 8.6 percent of reported health care–associated infections.[79,88] In one large academic hospital, the relative proportion of *Enterobacter* spp. in health care–associated infections had decreased as a result of an increase in gram-positive and anaerobic infections.[93] During a 10-year period in six Brazilian neonatal ICUs, gram-negative pathogens accounted for more than half of all bloodstream infections, with *Enterobacter* spp. representing 2 percent.[41] In Canada, similar results were found in a nationwide surveillance program, with *E. cloacae* found in 2.2% of all health care–associated infections, including blood, wound, and urine sources.[216] Multiple outbreaks caused by *Enterobacter* have been described in neonatal ICUs.[66,80,169] *E. cloacae* has been found in some neonatal ICUs as the predominant pathogen, representing almost 40 percent of bloodstream isolates,[119] in addition to being responsible for outbreaks of sepsis.[45] In some series, one third of *Enterobacter* bacteremias were polymicrobial, which represents a greater prevalence than that of bacteremia caused by other gram-negative organisms.[21,61]

The most frequently cited risk factor for *Enterobacter* infection is the recent receipt of antibiotics, particularly third-generation cephalosporins.* Other risk factors include prolonged hospital stay, especially in an ICU, presence of serious underlying illness (e.g., burns, malignancy, and diabetes); prematurity in a neonate; immunosuppression; organ transplantation; and the presence of a foreign device.† Vertical spread of *Enterobacter* from mother to infant may occur at the time of birth,[60] but infant colonization is usually from an environmental source. A surveillance program in a neonatal ICU that screens for *E. cloacae* colonization determined that only 8.8 percent of colonized infants were the result of mother-to-child transmission.[66] Environmental sources implicated in outbreaks of infection have included intravenous fluids,‡ chronic hand dermatitis of a care provider,[12] contaminated infant formula,[10,15,30,38,137] blood gas machines,[2,106] contaminated transesophageal echocardiography probes,[91] cardioplegia ice,[24] therapeutic bed mattresses and mattress covers,[190] and rectal thermometers.[189]

Ribotyping, pulsed-field electrophoresis, and restriction-fragment polymorphism analysis of DNA from clinical isolates have been useful in discriminating possible sources of contamination and patient-to-patient transfer of individual strains.§ Integrons, discrete mobile units of DNA that can confer antibiotic resistance, have been reported in *Enterobacter* spp. and are more common findings in infections acquired in a health care setting.[44] Molecular diagnostic testing has proved useful in outbreak situations, especially in tracking antibiotic-resistant strains caused by plasmid acquisition of extended-spectrum β-lactamases.[64] Most cases are not outbreak-associated, and endogenous origin of infection is a more common means of acquisition than is the patient's environment.[155] This factor explains why recent antimicrobial

use by the patient is such a strong predictor of infection.

PATHOPHYSIOLOGY

Newborns often are colonized by *Enterobacter* spp. in the gastrointestinal tract soon after birth,[14,145] and acquisition of hospital strains in immunocompromised newborns is common.[6,14,55,59,192] *Enterobacter* spp. may contaminate the compromised respiratory tract. The oropharynx commonly is colonized by *Enterobacter* by the time the infant is 1 month of age; colonization rates generally are lower in breast-fed infants.[11] Newborns with gastrointestinal abnormalities requiring prolonged parenteral nutrition have higher rates of colonization with *Enterobacter* and a higher incidence of sepsis.[156,157] Other risk factors for increased *Enterobacter* colonization in neonates include prematurity and prior antibiotic use.[150] Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults, but increased colonization, including increased risk for third-generation cephalosporin–resistant strains, especially with prior cephalosporin treatment of at least 3 days, is noted during illness.[204]

The ability of *Enterobacter* spp. to develop inducible resistance to penicillins and cephalosporins increases their pathogenic potential. All *Enterobacter* spp. possess an inducible chromosomally encoded class C (Bush group I) β-lactamase (*ampC*), which usually is produced in small amounts.[170] An inducible plasmid-encoded *ampC* (gene $bla_{\text{ACT-1}}$) also has been described and can be present in *Enterobacter* spp. and other Enterobacteriaceae.[168] Both enzymes have a high affinity for third-generation cephalosporins but a low maximum hydrolysis rate.[126] Consequently, β-lactamase mediates resistance to these antibiotics only when it is produced in large quantities or large numbers of plasmids are present.[113,164]

Resistance emerges after a mutation occurs in the *ampD* gene, which normally prevents high-level expression of β-lactamase.[87,90] Such mutants are considered "stably derepressed" and may be induced by exposure to β-lactam antibiotics, especially ampicillin and cephalosporins. Mutations in the *ampR* gene produce similar effects.[105] The addition of a β-lactamase inhibitor (e.g., clavulanic acid) does not increase the activity of β-lactam antibiotics against *Enterobacter* spp.; rather, it may decrease the activity against the organism by inducing the class C β-lactamase, as can the presence of *ampR* mutants.[90,105,193]

Emergence of resistance can occur during therapy for an isolate that initially is shown to be susceptible.[78,170] Resistance can be detected 24 hours after initiation of therapy or may be delayed 2 to 3 weeks.[36] In addition, more reports of resistant strains of *Enterobacter* that produce plasmid-mediated, extended-spectrum β-lactamases (ESBL) have been published.[84,121,158] Various ESBL genes, including genes from the TEM, SHV, and CTX-M families, have been found.[29,64,146,180,215] This variation can complicate choosing antimicrobial agents because discerning the source of the β-lactam resistance in the clinical microbiology laboratory often is difficult without performing specific testing, such as the double-disk diffusion method. A survey of 11 clinical laboratories in Germany to determine ESBL prevalence found that 40 percent of *E. cloacae* complex organisms were resistant to extended-spectrum cephalosporins, and only 6 percent carried ESBL genes.[84] This finding is in contrast to other reports with prevalences of 36 percent in some Asia-Pacific regions.[13]

The global spread of carbapenemase-producing Enterobacteriaceae has affected *Enterobacter* species, as well as other members of the class. Infections with these multidrug resistant organisms have been reported worldwide. Class A carbapenemases are plasmid mediated, effectively hydrolyze carbapenems, and are partially inhibited by clavulanic acid, with one of the most common being *Klebsiella pneumoniae* carbapenemases (KPC).[136] KPC-mediated resistance in *Enterobacter* spp. has been reported.[115,173] Class B metallo-β-lactamases (MBLs) are mostly Verona integron–encoded metallo-β-lactamase (VIM) and, more recently, New Delhi metallo-β-lactamase–1 (NDM-1). VIM producers can be endemic to a certain region, but have been reported globally in outbreaks and sporadic infections.[73,77,141] These enzymes hydrolyze all β-lactam antibiotics except aztreonam. NDM-1 producers have also been reported worldwide and are likely endemic in India. These genes are not associated with a single clone and have varied resistance to carbapenems. Of concern is the likelihood of other antibiotic resistance genes to be included on the $bla_{\text{NDM-1}}$ gene, including ESBL, aminoglycoside, macrolide, and rifampin resistance.[27,136] The CDC had three reports of NDM-1 isolates in 2010, one of which was *E. cloacae*. All patients had recent medical care in India as their risk factor.[33]

In one study, gram-negative fecal aerobic flora were eradicated completely after 24 hours of ceftriaxone therapy, only to be replaced within 10 days (mean, 6.7 days) of therapy by *P. aeruginosa*, *Enterobacter*, and *Citrobacter* resistant to all β-lactam antibiotics.[72] Although uncommon, the combination of reduced outer-membrane permeability and high-level β-lactamase production renders some clinical isolates of *Enterobacter* resistant to carbapenems (imipenem, meropenem, and ertapenem) and fourth-generation cephalosporins (cefepime).*

Other than the presence of endotoxin, factors responsible for the virulence of *Enterobacter* spp. are not well defined but may include cytotoxins, type III secretion systems, altered pili, and efflux pumps.† In vitro, it is possible to transfer and express an *Escherichia coli* enterotoxigenic plasmid in *Enterobacter*, implying the potential for transfer of virulence factors to *Enterobacter* spp. from other species.[214] Shiga toxin–producing *E. cloacae* has been isolated from the stool of a 5-month-old girl with hemolytic-uremic syndrome.[147] Shiga-toxin producing *E. coli* OR:H9 also was isolated from the child's stool, rendering the cause of the child's symptoms unclear. Similar to other organisms associated with central venous catheter infections, *Enterobacter* spp. may adhere irreversibly to catheter material, promoting colonization and infection via biofilm formation.[97,99,151] Certain ribotypes have

*References 19, 46, 49, 110, 112, 126, 152, 181, 187.
†References 95, 104, 109, 142, 144, 153.

been encountered more commonly as community or bloodstream isolates, indicating the presence of as yet undefined factors affecting virulence.[203] The propensity of *C. sakazakii* to produce neonatal meningitis complicated by abscesses and cerebral infarction is unexplained.[15,38,144,208] Proposed mechanisms have included brain capillary and intestinal endothelial cell invasion, persistence in human macrophages, biofilm formation, and a possible role for outer membrane protein A (OmpA).*

CLINICAL MANIFESTATIONS

Infection caused by *Enterobacter* commonly is indistinguishable from illness caused by other enteric pathogens. Sources of infection include central venous catheters and the urinary and biliary tracts.† *Enterobacter* commonly colonizes the respiratory tract secretions of intubated patients, and it is implicated increasingly as a cause of ventilator-associated pneumonia.[88,166,172] It can also be a cause of severe community-acquired pneumonia, generally in patients with serious comorbidities. This type of pneumonia strongly resembles health care–associated pneumonia, and patients may appear septic. Empirical antibiotic therapy may be very difficult because of unpredictable resistance patterns.[23] It also is one of the most common causes of pneumonia after lung transplantation[118] and can be found as part of the oral flora in patients with strokes.[70] Neonatal infection warrants special mention because of the prominence of *C. sakazakii* as a cause of devastating meningitis.

Similar to *Citrobacter koseri* (see Chapter 101), *C. sakazakii* causes neonatal meningitis complicated by cerebral abscesses or infarctions.‡ Poor feeding, irritability, jaundice, a full anterior fontanelle, and fever or hypothermia are presenting features shared with other gram-negative causes of bacterial meningitis. The mortality rate has been reported to range from 33 to 80 percent, and almost all survivors experience severe neurologic complications, including quadriplegia, developmental impedance, and impaired sight and hearing.[50,208] This severe morbidity is consistent with the development of multiple cystic lesions of the brain in 50 percent of surviving neonates. Serial computed tomography (CT) scans commonly reveal evolution of lesions most consistent with initial cerebral infarction, rather than primary abscess formation.[62,107,208] Subsequent cystic lesions may be purulent abscesses, from which the organism can be cultured; alternatively, they sometimes represent sterile fluid collections.[27] Meningitis tended to develop in infants of greater gestational age and birth-weight than in infants with only bacteremia, but they tended to be younger in chronologic age.[22]

Enterobacter also may be associated with necrotizing enterocolitis in the newborn, which became more apparent during the outbreaks of *C. sakazakii* associated with contaminated powdered infant formula.[107,188] *Enterobacter* spp. were the third most common isolate recovered from peritoneal fluid in a series of patients with necrotizing enterocolitis.[107,134]

In older immunocompromised children, bacteremia complicated by sepsis is a significant risk. Central venous catheterization and gastrointestinal tract pathologic processes seem to pose greater risks for development of bacteremia than infection of the urinary tract.[8,37,61,116] Bacteremia is accompanied by shock in almost one third of patients, but disseminated intravascular coagulation occurs in fewer than 5 percent.[17,21,61] Seeding of metastatic foci is uncommon. Overall case-fatality rates with bacteremia vary but usually are approximately 30 percent.[170] Predictors of poor prognosis include age younger than 18 months, inadequacy of antimicrobial chemotherapy, infection with extended-spectrum cephalosporin-resistant isolates, septic shock, type of underlying disease, presence of pulmonary infection, thrombocytopenia, unknown primary site of infection, and requirement for intensive care.* Absence of fever during the course of infection may be a particularly ominous sign; four of five afebrile subjects died in one series.[17] One study found that the use of an aminoglycoside as part of the empirical antibiotic management was a factor contributing to survival of *Enterobacter* or *Citrobacter* bacteremia.[47]

Some *Enterobacter* spp. recovered from children with diarrhea have been reported to produce enterotoxin,[35] although a causative role in enteritis has not been established. Other presentations of *Enterobacter* infection include endophthalmitis,[101,128,130] endometritis,[68] wound infections,[61] diskitis,[159,178] endocarditis,[186] and osteomyelitis.[40,51,100,179] *Enterobacter* also has caused syndromes classically associated with other agents, such as gas gangrene,[56] childhood purpura fulminans,[74] ecthyma gangrenosum,[160] and necrotizing fasciitis.[103]

DIAGNOSIS

Diagnosis of infection caused by *Enterobacter* relies primarily on isolation of the organism in culture from clinical material. Motility, production of ornithine decarboxylase, and the absence of deoxyribonuclease help distinguish the genus from *Klebsiella* and *Serratia*. The presence of yellow-pigmented colonies can help identify *C. sakazakii*. Patterns of sugar fermentation and production of decarboxylase also distinguish the species. Molecular techniques that are becoming available for rapid identification of bacteria include polymerase chain reaction (PCR)–single-strand conformation polymorphism analysis using 16S ribosomal DNA. This technique allows the potential identification of pathogens to be made from a wide range of clinical specimens with low numbers of bacteria.[206,212] Newer technology, including matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF) and real-time PCR for rapid nonculture detection of *Enterobacter* and other clinical isolates, are still under investigation.[124] These applications may have promise for clinical

*References 42, 97, 131, 133, 183, 184.
†References 8, 10, 61, 81, 88, 116.
‡References 15, 38, 50, 94, 208, 210.

*References 17, 21, 34, 47, 61, 92, 122.

applications.[149,167] In light of the increase of *C. sakazakii* invasive disease after ingestion of contaminated powdered infant formula, several techniques have been introduced for the rapid identification of this pathogen clinically and in foodstuffs. The use of a specific PCR amplification of the outer membrane protein A gene *(ompA)* is being investigated,[132] as is reverse-transcriptase[114] and the use of selective media.[5,48,98] DNA microarray technology is also being investigated for use.[198] Ribotyping is a highly discriminatory and reproducible method for the typing of *E. cloacae*, the most common cause of infection.[63] Other useful molecular techniques include restriction endonuclease analysis of chromosomal DNA, pulsed-field gel electrophoresis, random amplification of polymorphic DNA, and amplification of short interspersed repetitive sequences.[170] Most often, molecular typing methods are used in concert with biotyping, serotyping, or bacteriocin typing.

TREATMENT

Treatment of *Enterobacte*r infection is made problematic by inducible resistance to cephalosporins and intrinsic resistance to aminopenicillins, cefazolin, and cefoxitin.[20] The recognition that *Enterobacter* spp. may carry ESBL plasmids in addition to expressing chromosomal *ampC* β-lactamases can be problematic using automated ESBL detection systems. The use of the double-disk synergy method for ESBL detection can indicate the presence of plasmid-mediated resistance but is challenging because high production of *ampC* can mask the inhibition of ESBL by clavulanic acid.[207] New selective media for the identification of ESBL-producing isolates are available, but still may have problems with high *ampC* producers.[161,163] Identification of carbapenemase-producing isolates is more difficult. The Clinical and Laboratory Standards Institute (CLSI) lowered carbapenem breakpoints in the United States in 2010 to allow for better identification, but this has not occurred in Europe. The modified Hodge test has potential, but like the double-disk synergy method for ESBL detection, it is manual and can be time consuming, while still lacking in specificity and sensitivity (i.e., allows detection of high level *ampC* producers, but with weak detection of NDM-1 producers). Molecular techniques, mostly PCR, are now the standard for detection.[136] It is important to know the local antibiotic resistance patterns to determine the risk for multidrug resistance. Therapeutic options in this setting can include the use of older medications, including fosfomycin and colistin, in addition to newer antibiotics such as tigecycline and doripenem.[67]

Antibiotic resistance may be present at the time of initial isolation or may develop during therapy.[37,78] This problem is compounded by the common observation of resistance to extended-spectrum penicillins and, to a lesser extent, aminoglycosides.[7] The risks for development of resistance to cephalosporins, piperacillin, and aminoglycosides have been reported to be higher at a tertiary care center than at a primary care hospital.[54] Previous administration of third-generation cephalosporins increases the risk for having multiresistant *Enterobacter* isolates in an initial positive blood culture.[8,36,135] Hospitalized newborns quickly may acquire multiresistant strains, even though they themselves have not been treated with cephalosporins.[14] Isolation of multiresistant *Enterobacter* spp. in blood culture is associated with a higher case-fatality rate in contrast to mortality after isolation of a more sensitive *Enterobacter*.[36,175] Although less common, resistance to imipenem has been reported.[53,110,182] Cefepime, a fourth-generation cephalosporin, generally maintains activity against *Enterobacter* spp. that possess the class C β-lactamase,[171] although minimum inhibitory concentrations may be higher.[126]

Emergence of cefepime resistance during therapy has been described in a liver transplant recipient with a hepatic abscess caused by *E. aerogenes*.[112] The accompanying editorial warns about the risk for failure using cefepime in patients who have high-density infections (e.g., poorly drained liver abscess) caused by ceftazidime-resistant strains of *Enterobacter*.[126] The presence of an SHV-type ESBL has been associated with cefepime resistance, highlighting the need to identify those strains.[178] Vigilant antibiotic stewardship may aid in decreasing resistance. One institution restricted the use of cefepime and compared the 2 years before with the 2 years after the policy, demonstrating an improvement in ciprofloxacin susceptibility in their *Enterobacter* clinical isolates.[140]

In a nationwide survey of nosocomial bloodstream infections, rates of *Enterobacter* resistance to third-generation cephalosporins (ceftazidime, ceftriaxone) and broad-spectrum semisynthetic penicillins (piperacillin) with or without a β-lactamase inhibitor (tazobactam) was high, ranging from 35 to 50 percent.[155] Cefepime and imipenem inhibited 97 to 100 percent of isolates. Susceptibility to aminoglycosides and fluoroquinolones ranged from 92 to 98 percent, and 85 to 96 percent of isolates were susceptible to trimethoprim-sulfamethoxazole. Fluoroquinolone resistance is now being reported and likely is plasmid-mediated.[143,213] Plasmid-mediated quinolone resistance can be more common in ESBL-producing isolates as well, so caution should be used.[177] Because resistance patterns may vary based on geographic location, local susceptibility data should be used to guide initial therapy.

Some investigators recommend initial combination therapy that includes an aminoglycoside plus either cefepime or a carbapenem (imipenem or meropenem), until results of susceptibility testing are available. Third-generation cephalosporins should be used with caution, even when initial susceptibility results seem favorable. When strains are resistant to gentamicin and tobramycin, amikacin may be a suitable alternative. Good responses to therapy and return of gentamicin susceptibility of hospital *Enterobacter* strains have occurred after routine substitution of amikacin for gentamicin.[162,176] Trimethoprim-sulfamethoxazole alone (or combined with an aminoglycoside) and quinolones seem to be good alternatives for the treatment of *Enterobacter* infections, including meningitis.[8,43,69,127,210] Fluoroquinolones have been reported to be effective in bone and joint infections, in combination with cefepime.[111] As newer antimicrobial agents become available, more testing will be required to determine their effectiveness. Tigecycline has promise,

especially in the treatment of multidrug resistant strains.[196,211] Colistin has also been used, but it is hampered by its side effect profile.

Enterobacter meningitis creates special concerns. As is common with other forms of neonatal enteric meningitis, even susceptible organisms often persist in cerebrospinal fluid for 5 days or longer.[94] Monotherapy with a cell wall–active agent seems to be less effective than combination therapy with an aminoglycoside. Trimethoprim-sulfamethoxazole also has been used successfully.[58,210] Intrathecal administration of antibiotics does not seem to be beneficial in infants,[125] but it has been used with some success in adults.[139] The physician should anticipate the potential development of cerebral abscesses, infarctions, and cysts in newborns with *C. sakazakii* infection. Serial CT scans should be considered, and a neurosurgeon should be sought for drainage of abscesses and management of fluid accumulation.

CHAPTER 103

EXTRAINTESTINAL PATHOGENIC *ESCHERICHIA COLI*

Patrick C. Seed

Escherichia coli are common among terrestrial mammals, including humans, occupying approximately 0.1 percent of the microbes in the human enteric tract.[25] Although *E. coli* has normal homeostatic functions within intestinal-associated microbial communities, some subtypes have developed the capacity to invade other niches and produce infectious diseases.[59,69] Genetic mutations and the loss and gain of genetic material through genetic rearrangements, transposons, phages, and plasmids have produced *E. coli* lineages with a wide capacity to occupy different host niches and yield different clinical syndromes.[69] Animal and human subtypes are closely related and in many cases are the same, differentiated based only on the hosts from which they were isolated. The pathotypes of *E. coli* have specific associated virulence factors and genetic islands.

E. coli is the common cause of a wide range of bacterial infections within and outside of the intestinal tract, including traveler's diarrhea, dysentery, cholecystitis, cholangitis, urinary tract infection, bacteremia, neonatal meningitis, and pneumonia (Table 103-1). The pathogenic *E. coli* may be divided into two major categories: extraintestinal pathogenic *E. coli* (ExPEC) and diarrheogenic *E. coli*. ExPEC will be the focus of this chapter.

Escherichia coli are facultative anaerobic gram-negative bacilli in the Enterobacteriaceae family.[40] Common physiologic and biochemical features include fermentation of lactose (~90% of isolates), indole production, and lysine decarboxylase activity.[77] Many isolates are motile, with peritrichous flagella constituting 1/56 flagellar antigen (H) serotypes.[75] In addition, there are 171 somatic antigens (O). The most common O subtypes have been reported as O1, O2, O4, O6, O7, O8, O18, O25, O68, and O75.[14,36,107,132]

EPIDEMIOLOGY

E. coli produces three major types of extraintestinal invasive diseases in children: (1) urinary tract infections (UTIs), (2) bacteremia and sepsis, and (3) meningitis. Lower incidence infections produced by ExPEC include pneumonia, osteomyelitis, and endocarditis. Antibiotic resistance in ExPEC has undergone a shift in the past

TABLE 103-1 **Major *Escherichia coli* Classifications**

Main Group	Subgroup	Associated Diseases
Intestinal pathogenic *E. coli* (IPEC)	Enterohemorrhagic *E. coli* (EHEC)	Afebrile, bloody colitis
	Enteropathogenic *E. coli* (EPEC)	Watery diarrhea
	Enterotoxigenic *E. coli* (ETEC)	Watery diarrhea
	Enteroaggregative *E. coli* (EAEC)	Chronic, persistent diarrhea
	Enteroinvasive *E. coli* (EIEC)	Watery diarrhea or dysentery
Extraintestinal pathogenic *E. coli* (ExPEC)	Uropathogenic *E. coli* (UPEC)	Urinary tract infection, urosepsis
	Neonatal meningitis *E. coli* (NMEC)	Meningitis
	Sepsis-causing *E. coli* (SEPEC)	Bacteremia, sepsis
Animal-associated pathogenic *E. coli* (AAPEC) reservoir groups	Avian pathogenic *E. coli* (APEC)	Bird sepsis, chronic respiratory disease, swollen head syndrome
	Mammary pathogenic *E. coli* (MPEC)	Bovine mastitis
	Endometrial pathogenic *E. coli* (EnPEC)	Bovine endometriosis

TABLE 103-2 **Risk Factors for Extraintestinal Pathogenic *Escherichia Coli* Urinary Tract Infection in Children**

Factor	Type	Mechanism	References
Female gender	Physical-anatomic	Shorter urethra and closer proximity to the rectum increases access of uropathogens to the urinary tract	139
Vesicoureteral reflux	Physical-anatomic	Reflux of urine through the ureteral valves moves contaminated urine from the bladder to the kidneys	7, 11, 117
Bladder dyssynergia	Physical-anatomic	Incoordination of voiding; failure to clear microbes	120
Urinary tract anomalies	Physical-anatomic	Urinary stasis; failure to clear microbes	7
Catheterization	Physical-anatomic	Introduction of organisms into urinary tract; persistence of less virulent organisms	73, 112, 126
Sexual intercourse	Behavioral	Introduction of periurethral organisms into urinary tract	26, 91
Spermicide use	Behavioral	Inhibition of vaginal lactobacilli with outgrowth of *E. coli*	45
Diaphragm use	Behavioral	Spring-rim–mediated minor bladder trauma; co-use of spermicidal gels	45
Diabetes mellitus	Immune	Glucosuria; neutrophil functional impairment	32, 93, 98

decade and has important implications in the treatment of ExPEC-related infections.

Urinary Tract Infection

E. coli is the leading cause of culture-proved UTI in children, producing more than 80 percent of community-acquired UTI, regardless of the presence of vesicoureteral reflux.[44] Other etiologies in pediatric community-acquired UTI include *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterococcus* spp., and, primarily in female adolescents, *Staphylococcus saprophyticus*. *E. coli* is also the leading cause of hospital-acquired UTI among children. Unlike in adult patients, in whom *E. coli* may account for more than 50 percent of nosocomial UTIs, *E. coli* produces approximately 30 percent of nosocomial UTIs in children.[72,79] Organisms such as *Candida* spp., *Klebsiella* spp., and *Pseudomonas aeruginosa* assume a greater proportion of pediatric nosocomial UTIs.

In general, the prevalence of UTI is 7 percent among infants with febrile illness, of which, as noted earlier, *E. coli* is by far the most likely cause.[116] Among female infants, 7.5 percent with febrile illnesses have a UTI. Of male infants, the prevalence differs greatly based on whether the infant was circumcised. Among uncircumcised male infants, the prevalence of UTI is 20.1 percent, in contrast to a prevalence of 2.4 percent among those who are circumcised. Circumcision status does not alter the high proportion of UTIs associated with *E. coli*. Black infants have a lower prevalence of UTI, at approximately 4.7 percent, in contrast to white children, at 8 percent. The prevalence of UTI drops significantly after the age of 1 year but increases during adolescence such that the pooled prevalence among children younger than 19 years of age is 7.8 percent.[116] Factors increasing the risk for urinary tract infection include vesicoureteral reflux, bladder dyssynergia, other urinary tract anomalies, sexual intercourse, spermicide use, pregnancy, and diabetes mellitus (Table 103-2).

Fever without localizing signs is a major cause of presentation for medical care among infants younger than 90 days of age. Recent studies indicate that in the era of vaccinations for *Haemophilus influenza* type b and *Streptococcus pneumoniae*, *E. coli* UTI is the leading cause of

fever without localizing signs.[133,134] UTI was responsible for 76 percent of all episodes, and bacteremia and meningitis were 19 percent and 3 percent, respectively. Of the UTIs, *E. coli* was the causative agent in 96 percent of the cases.

Some female children experience colonization of the bladder without urinary symptoms, termed asymptomatic bacteriuria (ASB). *E. coli* is also the most common cause of ASB. In U.S. female school children at 5 to 6 years of age, the incidence of ASB was observed to be 1.9 to 2.2 percent, whereas only 0.2 percent of age-matched boys had ASB.[20,113] The cumulative prevalence of ASB between the ages of 6 and 12 years is reported to be 4.6 percent. No ethnic or socioeconomic risk factors have been associated with ASB. In addition to sex, risk factors include diabetes and sickle cell disease.[17,106]

Bacteremia and Sepsis

E. coli may produce bacteremia or sepsis. Pediatric *E. coli* bacteremia and sepsis occur mostly in young infants and special groups of children such as patients with chemotherapy-induced immunodeficiency, central venous catheters, urinary tract anomalies, and human immunodeficiency virus.[16,108] Patients in the neonatal and pediatric intensive care units have a heightened risk for bloodstream *E. coli* infections, as do patients with obstructive urinary tract disease and UTI, leading to urosepsis.

Among infants, *E. coli* bloodstream infections are most common in the first month of life, with decreasing numbers of cases in the second to third months of life. Among neonates, *E. coli* has been associated with approximately 18 percent of early-onset sepsis and a similar percentage of late-onset sepsis, placing it as the second or third most common etiology in this age group.[130] In preterm infants, the infection rate for *E. coli* was over 10 percent, with a contemporary study demonstrating a rate of 29 percent.[9,123] Prematurity, low birth-weight, prolonged labor, prolonged rupture of membranes, intrapartum maternal fever, and maternal antibiotics may increase the risk for complicated, high morbidity or mortality infections.[128] Neonatal early-onset group B streptococcal disease has decreased significantly with the use of intrapartum ampicillin for women at risk because of known colonization, prolonged rupture of membranes, or maternal fever. However, more than 50 percent of *E. coli* organisms are resistant to ampicillin such that prophylaxis has not had a positive impact on early-onset *E. coli* infection. Retrospective data suggest that ampicillin-resistant *E. coli* may be responsible for more fulminant and higher mortality disease among premature infants,[1,9,55] although this remains controversial and in need of further study.[115]

Meningitis

In the pediatric population, *E. coli* meningitis occurs almost exclusively among young infants and highly immunocompromised children. It is the leading cause of meningitis among preterm infants and equal to group B streptococcus.[19,122] *E. coli* meningitis frequently results in intensive care, severe neurologic impairment, and high mortality, at 34 percent, 21 percent, and 14 percent, respectively.[48,49] Twenty-eight percent of infants have intercurrent UTI and are older than 6 days of life.[48] Concurrent bacteremia is present in 81 percent.

Peritonitis

Peritonitis in children is most typically a complication of appendicitis. Intestinal perforation is an infrequent cause in children. Overall, it is a rare entity in children in contrast to adults. *E. coli* accounts for more than 50 percent of bacterial peritonitis in children, with 60 percent of the infections being polymicrobial.[23]

Pneumonia, Endocarditis, and Osteomyelitis

E. coli is an infrequent cause of infections of the lungs, heart, and bones. Pneumonia may arise from oropharyngeal or hematogenous sources and endocarditis through hematogenous spread after translocation of bacteria from the intestinal tract or following urosepsis. Osteomyelitis is most frequently hematogenous after intestinal translocation or urosepsis but also may occur after traumatic injuries and direct inoculation into areas proximal to bone.

PATHOGENESIS

ExPEC produces a wide variety of invasive infections outside of the gastrointestinal tract, including those of the urinary tract, bloodstream, and central nervous system (CNS). ExPEC is a normal commensal organism in the enteric and genital tracts, and colonization alone does not have any measurable consequence to individuals harboring these strains. ExPEC colonizes through oral-fecal transmission where food may be contaminated, through cross-transmission between humans, or, as more recently described, through transmission between domesticated animals such as cats and dogs.[53] Sexual transmission of ExPEC also has been shown to occur, with male partners appearing to transmit ExPEC bearing virulence gene characteristics typical of those producing UTIs to their female partners.[28] The relative frequency of acquisition of ExPEC by oral-fecal and sexual routes is not clear at the present time.

ExPEC infections occur after bacteria invade sterile sites such as the urinary tract or the bloodstream from commensal reservoirs such as the enteric tract and vagina. When the immune system is unable to limit the spread of bacteria, invasive infections such as UTI, bacteremia, meningitis, and, more rarely, pneumonia or osteomyelitis may occur.

Urinary Tract Infection

ExPEC is the leading cause of UTIs,[27] and UTI may precede more invasive infections of the bloodstream, bones, heart, and CNS. ExPEC colonizing the

periurethral area may be introduced into the urethra and ascend through the urinary tract. The infection may involve only the urethra (urethritis), but most commonly involves the bladder, resulting in cystitis. More advanced infections may ascend through the ureters to the kidneys, resulting in pyelitis, pyelonephritis, or pyelonephrosis. Anatomic variation or defects, such as voiding dysfunction and vesicoureteral reflux, increase the risk for lower tract and upper tract UTI.[30]

Infrequently, ExPEC UTI may occur through hematogenous spread in which bloodstream organisms infect the kidneys and are subsequently isolated from the urine in a descending infection. This may occur during bacteremia after organisms have translocated from the enteric tract. Perinephric abscesses may be the sole consequence of hematogenous infection of the urinary tract.

The specific host and bacterial factors that favor transition from the external genital region into the urethra remain poorly understood in the prepubescent, nonsexually active child. After the initiation of sexual activity, UTI rates increase.[27] Spermicides and intercourse are both associated with an increased risk for UTI in women, primarily through promotion of ExPEC in the vagina and mechanical introduction of bacteria into the female urethra, respectively. The size of the inoculum necessary to start an infection in humans is not well understood and is likely overestimated in animal models.

Many of the molecular events during ExPEC cystitis have been recently elucidated through animal and human studies (Fig. 103-1), and ExPEC produces virulence factors to persist in the urinary tract (Table 103-3). Once in the urinary bladder, ExPEC adheres to the bladder epithelium to initiate an infection. Attachment is essential because micturition is a potent host defense to flush the bacteria out of the organ.[135] Type 1 pili, fibrous extensions from the bacteria with adhesive tips, have been established as a major *E. coli* factor promoting adherence to the bladder epithelium. On attachment of ExPEC to the apical surface of the bladder epithelium via type 1 pili, ExPEC can invade into bladder epithelial cells through a variety of routes, including lipid rafts and caveolin, clathrin-coated pits, and fusiform vesicles.[8,24,61] Within the epithelium, ExPEC may persist long-term in late endosomes[86,87] or escape into the cytosol of the epithelial cell and form intracellular bacterial communities (IBCs), biofilm-like structures with bacteria enmeshed in type 1 pili, aggregative antigens, and polysaccharide capsules.[3,4] From the IBC state, bacteria may amass and escape as long filaments, only to bind to more bladder epithelial cells and reinvade naïve epithelium.[56,57]

ExPEC isolates from children with pyelonephritis are more likely to produce P pili, hemolysin, and cytotoxic necrotizing factor (CNF-1) and be serum resistant than cystitis strains or commensal isolates.[21,49] In the kidneys,

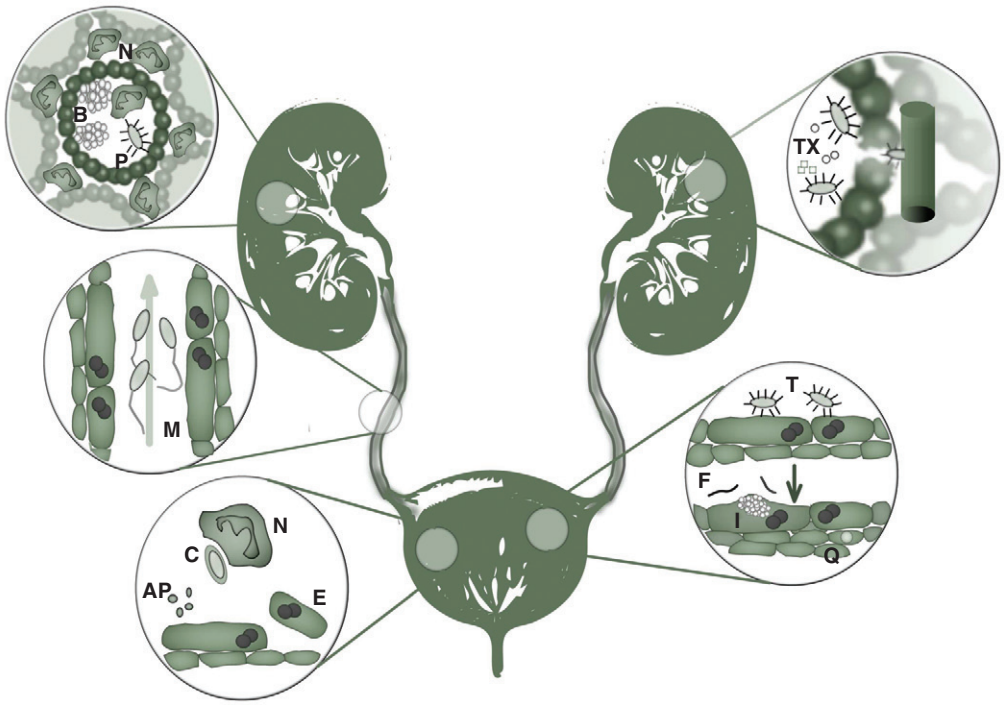

FIGURE 103-1 ■ Pathogenesis of extraintestinal pathogenic *E. coli* (ExPEC) urinary tract infection. ExPEC produces lower and upper tract infection. In the bladder, *E. coli* adheres to the bladder epithelium by using adherence factors such as type 1 pili *(T, lower right circle).* ExPEC can invade the epithelium, replicate, and reemerge as filamentous bacteria *(F).* Infection of the bladder results in a strong inflammatory response *(lower left circle)* involving production of antimicrobial peptides *(P),* neutrophil infiltration *(N),* and exfoliation, or sloughing, of the epithelium *(E).* ExPEC produces a capsule *(C)* to protect against the innate immune response. ExPEC can migrate up the ureters *(middle left circle)* against urinary flow using flagella *(M).* In the kidneys, ExPEC produces P pili *(P)* and other adhesive factors to bind to the renal epithelium, where biofilms *(B)* may be formed. An inflammatory response includes neutrophils *(N)* and other factors such as complement and antimicrobial peptides. From the kidney tubules, ExPEC may also produce toxins *(TX, upper right circle),* damaging the local epithelial and endothelial borders to invade capillaries and disseminate in the bloodstream, producing bacteremia. (See companion website on Expert Consult for a color version of this figure.)

TABLE 103-3 **Representative Extraintestinal *Escherichia Coli* Virulence Factors**

Functional Category	Virulence Factor	Role	References
Adhesin	Type 1 pili *(fim)*	Adherence to urinary tract epithelium, particularly in bladder; lectin-recognizing mannosylated glycoproteins	50, 51, 62
	P pili *(pap/prf)*	Adherence to urinary tract epithelium, particularly in bladder; lectin-recognizing glycolipids	70, 78, 105, 129
	S pili *(sfa/foc)*		135
	Auf pili		15
	Dr adhesins	Examples include Dr and Afa I-IV; binding to decay-activating factor	33, 95
	TosA	Repeats-In-Toxin (RTX) protein; adherence to renal tubular cells	131
	UpaB	Autotransporter-type adhesion; binding to extracellular matrix proteins	2
	Tsh	Serine protease-type autotransporters; associated with pyelonephritis strains	42
Invasin	IbeA	Invasion of the brain endothelium	54, 78
	OmpA	Outer membrane protein A	92
Toxins	HlyA	α-Hemolysin	83
	Cyclomodulins	Examples include cytolethal distending toxin (CDT-1) and cytotoxic necrotizing factor 1 (CNF-1)	22
	Sat	Serine autotransporter	37
Protectins	Groups II and III polysaccharide capsules	K1, K2, and K5 capsules, among others	3, 5
	OmpT	Outer membrane protease T	124
	Curli	Amyloid-like extracellular fibers	58
Iron acquisition	IreA	Siderophore receptor	31
	Iro	Salmochelin	31
	Iuc	Aerobactin	31
	SitA	Periplasmic iron binding protein	31
	Ybt	Yersiniabactin	31
Immune regulators	TcpC	Immunomodulator	78
	SisA/B	Inflammation suppressors	76
Other	DsdA	D-Serine deaminase	39
	Flagella	Motility	71, 136
	Cellulose	Biofilm formation	94

ExPEC uses Ppili and type 1 pili to adhere to the renal tubule epithelium and persist in the kidney.[70,81] Local toxin production, including hemolysin, CNF-1, and Sat, damage the epithelium and may permit bacterial penetration and translocation across the border into the adjacent capillary system.[80,119] The toxins also may inhibit infiltrating granulocytes and limit their capacity to contain the infection.[18]

In response to acute infection of the bladder, the lipopolysaccharide-recognition receptor Toll-like receptor 4 (TLR4) is triggered by ExPEC, initiating a signal cascade that results in proinflammatory events, including the expression of cytokines interleukin (IL)-6, IL-8, and granulocyte-macrophage colony-forming unit (GM-CSF).[41,121] Neutrophils and macrophages are recruited into the bladder to assist in clearing the infection.[68,137] The superficial bladder epithelium is also shed in the process of exfoliation, resulting in elimination of attached and invasive intracellular ExPEC. Microscopy of urine from young women with acute cystitis revealed leukocytes and exfoliated bladder epithelial cells, including filamentous ExPEC and cells harboring IBC.[110] In animal studies, the clearance of ExPEC is incomplete, even with the application of antibiotics, resulting in chronic latent intravesical infection, predicted to be a reservoir for some recurrent infections.[87,114]

The determinants that balance acute inflammatory infections and ASB are not fully known. ASB and cystitis isolates have reduced virulence gene numbers relative to strains causing pyelonephritis.[10,125] Despite similar known virulence gene content in cystitis strains of ExPEC, a prototypic ASB isolate of *E. coli* has been previously shown to have reduced virulence factor gene expression in contrast to cystitis isolates and ASB isolates may outcompete cystitis strains for growth in urine.[109] The host response to bacteria within the urinary tract is likely to be important to the development of ASB. Children with reduced TLR4 expression have been shown to have an increased risk for ASB.[104]

Bacteremia

ExPEC are frequent causes of bacteremia secondary to translocation from the intestinal tract into the

bloodstream. This frequently occurs in patients with loss of intestinal epithelial barrier integrity or compromised immunity. ExPEC produces protective factors that favor survival in serum, including polysaccharide capsules known to inhibit complement deposition, opsonization, and phagocytosis by granulocytes.[12,47,111] Toxins such as hemolysin A and CNF-1 have roles in inhibiting phagocyte function,[18,103] thus limiting ExPEC clearance. ExPEC also responds to the bloodstream environment by downregulating factors that may stimulate immunity or promote phagocytosis such as the adhesive factor type 1 pili.

Critical metabolic pathways are necessary for successful dissemination of ExPEC in bloodstream infections. Sialic acid usage and iron acquisition have been previously shown to be essential for ExPEC survival during disseminated infection.[118]

Meningitis

ExPEC disseminates from mucosal surfaces through the bloodstream to the CNS. Neonatal animal models have suggested that ExPEC disseminates to the CNS within macrophages and that dissemination depends on nitric oxide production.[82] The severity of bacteremia correlates with the likelihood of developing meningitis in both infant and adult animal models.[67] At the blood-brain barrier, ExPEC transverses the brain microvascular endothelial cells by first binding and invading the cells through actin rearrangement and transcellular traversal of the barrier.[66] Type 1 pili and OmpA (Table 103-4) are key adhesive factors mediating the initial interaction between *E. coli* via CD48 and gp96, respectively.[64,102] The *E. coli* factor IbeA has been shown to enhance brain microvascular endothelial cell invasion.[29,101] K1 polysaccharide encapsulation, common among ExPEC causing neonatal meningitis prevents late endosome–lysosomal fusion and thus killing of intracellular *E. coli*, whereas lack of encapsulation results in bacteria proceeding through early to late endosomes and lysosomal fusion with eventual degradation of the bacteria-containing vacuoles.[65] The consequence of brain endothelial cell invasion by *E. coli* is blood-brain barrier dysfunction resulting from cytokine release such as the proinflammatory factor IL-8, brain endothelial cell apoptosis, and increased permeability, ultimately leading to encephalopathy.[66]

TABLE 103-4 **Susceptibility to Antibiotic-Class Representative Agents Commonly Used in the Treatment of Urinary Tract Infection and Invasive *Escherichia Coli* Infections**

CLINICAL PRESENTATION

Urinary Tract Infection

Acute UTI with *E. coli* is associated with dysuria, urinary frequency, urgency, and often cloudy or odorous urine. Cystitis typically has low-grade fever or no elevation in temperature and may include anterior abdominal or pelvic pain or pressure. In contrast, *E. coli* pyelonephritis includes flank or lower back pain, and high fever, often higher than 38.9°C (102°F). Pyelonephritis may also include chills, sweats, rigors, nausea, vomiting, and headache. In patients with perinephric abscesses or intrarenal necrosis, the patient may have pleuritic chest pain from irritation of the diaphragm, and a flank mass may be present on physical examination. Bacteremia and urosepsis may develop secondary to pyelonephritis, especially among patients with diabetes, urinary tract abnormalities, urinary obstruction, or pregnancy. Pyelonephritis with and without urosepsis must be differentiated from intra-abdominal processes, including appendicitis, psoas abscess, ruptured ovarian cyst, and ectopic pregnancy.

E. coli UTIs are not easily distinguished symptomatically from the syndromes caused by other organisms, including *S. saprophyticus* in the female adolescent, *K. pneumoniae*, *P. mirabilis*, or group B streptococcus.

Bacteremia and Sepsis

Bacteremia by *E. coli* is not readily distinguished in signs and symptoms from bloodstream infections produced by other gram-negative bacteria. Children may have fever, fatigue, lethargy, or irritability. Nausea and vomiting may accompany bloodstream infections. Some children may have a diffuse erythematous rash and, in the case of sepsis, generalized edema. Tachycardia may occur in the presence and absence of fever. Urine output may be diminished accompanying renal failure in cases of severe infection.

Meningitis

Neonates with *E. coli* meningitis present with general nonspecific features, including fever, vomiting, irritability, and failure to thrive. In advanced circumstances,

neurologic signs, including apnea, seizures, decreased muscular tone, and ocular or limb palsies, may be present. Jaundice may accompany the presentation. In the infant older than 3 months, nuchal rigidity and a tense fontanelle may be part of the presentation. Acute *E. coli* meningitis in the older child is accompanied by headache, nausea, vomiting, lethargy, confusion, and fever. Neurologic features such as seizure or focal symptoms may accompany *E. coli* meningitis. The clinical presentation of *E. coli* meningitis overlaps with other etiologies of meningitis.

E. coli meningitis may be a rare complication of neurosurgical procedures. The clinical presentation may not be different from that of acute meningitis in the nonsurgical patient. However, infectious meningitis must be differentiated from other infectious and noninfectious complications of surgery.

Acute *E. coli* meningitis must be differentiated from other processes, including seizure disorder, brain abscess, aneurysm, sepsis, and, in the case of the neonate, tetanus.

Intra-abdominal Infection

E. coli produces cholecystitis and cholangitis associated with right upper quadrant pain, fever, and jaundice. In advanced cases, bacteremia and sepsis may complicate the infections. Both infections are associated with high fever, typically above 38.9°C (102°F). Cholangitis is accompanied by chills and sometimes hepatic abscess. Children with *E. coli* cholecystitis or cholangitis develop right upper quadrant pain, fever, and jaundice. In severe cases, hypotension and confusion also develop. Cholecystitis manifests with fever (>38.9°C [102°F]). Cholangitis manifests with fever (>38.9°C [102°F]), shaking chills, and right upper quadrant pain and can be complicated by hepatic abscess. Other infectious etiologies may bear resemblance to *E. coli* intra-abdominal infection, including *Klebsiella* spp., enterococcus, and, with appropriate exposure histories, amoebic abscess or *Echinococcosis* spp.

E. coli also may cause intra-abdominal abscesses with and without peritonitis. Abscess alone may be associated with low-grade fever and nonspecific abdominal pain, as well as occasional malaise and anorexia. Peritonitis is associated with higher fever and rebound pain. In severe cases, septic shock may accompany peritonitis. Patients with *E. coli* intra-abdominal abscesses may have low-grade fever, but the spectrum of clinical presentations ranges from nonspecific abdominal examination findings to frank septic shock. Peritonitis manifests as localized pain with rebound and fever. Abdominal abscess with E. coli are often polymicrobial with anaerobes, gram-negative bacilli, and enterococci.

Pneumonia

Children with *E. coli* pneumonia typically present with a febrile illness, shortness of breath, tachypnea, increased respiratory secretions, and rales and crackles with auscultation. *E. coli* pneumonia may be ventilator-associated and bacteremia-associated. *E. coli* is a rare cause of community-acquired pneumonia in a child with otherwise normal immune defenses. *E. coli* pneumonia is difficult to distinguish clinically from other bacterial pneumonia.

DIAGNOSIS

General

The definitive diagnosis of ExPEC infection is isolation of the organism from a sterile site such as urine, blood, or cerebrospinal fluid (CSF). Isolation from sputum or wounds is also indicated in some circumstances, such as pneumonia and abdominal infections, respectively. In these circumstances, recovery of the bacterium must be regarded in the context of the patient's clinical presentation to determine if the isolation of the organism is compatible with infection or represents colonization.

E. coli is readily isolated from a wide variety of clinical samples at 37°C (98.6°F) and aerobic conditions.[40] Nonselective and selective media, including MacConkey agar, will isolate *E. coli*. Approximately 90 percent of isolates are lactose fermenting, and approximately 99 percent produce indole, making this an optimal biochemical test for the identification of *E. coli*.[89] Many isolates are β-hemolytic, although a significant percentage from sites such as the urinary tract may not display β hemolysis on blood agar. *E. coli* does not typically produce pigments.

Urinary Tract Infection

For suspicion of UTI, a urine dipstick test may be performed to rapidly determine if the patient has pyuria or bacteriuria based on the detection of leukocyte esterase and nitrites, respectively. Definitive diagnosis is based on urine culture results. The specimen should be collected from a midstream clean void in children old enough to provide such a sample or by straight sterile catheterization in younger children. A contaminated specimen and asymptomatic colonization must be differentiated from infection based on clinical symptoms and signs, as well as the urinalysis consistent with inflammation. In cases of infection, pyuria usually is present. In urinalysis, leukocyte esterase and nitrite each have a sensitivity of 0.88 and a false positive rate of 0.05. Bacteria identified by Gram stain on noncentrifuged samples have a sensitivity of 0.93 and false positive rate of 0.05. White blood cells alone have poor sensitivity and increased false positive rate.[34]

Routine screening of the urine for cure after antibiotic therapy and screening for asymptomatic colonization are not recommended because screening produces a large number of false positive results and does not alter rates of renal scarring.[60,63]

Imaging studies may be indicated in some patients to assist in making a diagnosis of *E. coli* infection, determining the necessity for an interventional procedure, or assessing the prognosis. For UTI, renal ultrasonography, computed tomography, or dimethylsuccinic acid scans

may be indicated to evaluate the kidneys and look for any other source of abscess, stones, or obstruction. Vesicoureterogram may be indicated for the diagnosis of vesicoureteral reflux, which may predispose a patient to pyelonephritis.

Other Infections

Recovery of the organism in contaminated sites, such as sputum and wounds, must be analyzed in the context of the patient's clinical state to determine if it represents colonization or infection. Recovery from sterile sites, such as the CSF, should be considered diagnostic of infection.

Lumbar puncture and a CSF culture for *E. coli* will establish the diagnosis of acute *E. coli* meningitis. Before culture data are available, CSF parameters alone will not be specific for *E. coli* infection. Elevated protein, depressed glucose, and the presence of leukocytes with a neutrophilic predominance may be present. Before culture information is available, Gram stain may reveal gram-negative bacilli without being solely indicative of *E. coli*. Justification for this lumbar puncture and analysis must be made based on indications for possible CNS infection, including a positive blood culture, altered behavior, and abnormal neurologic signs, such as seizure.

Patients with pneumonia should undergo blood cultures and sputum Gram stain and culture. The results of a Gram stain of the sputum help differentiate a good specimen (i.e., many polymorphonuclear [PMN] leukocytes and few squamous epithelial cells) from a bad specimen (i.e., few PMN leukocytes and many squamous epithelial cells). In addition, obtain the sputum culture before antibiotic therapy is initiated.

Additional studies may be indicated for non-UTI ExPEC infections. In pneumonia, chest radiography or CT is indicated. In cholecystitis and cholangitis, ultrasonography or CT of the right upper quadrant is indicated. For suspicion of intra-abdominal abscess, abdominal and pelvic ultrasound or CT may be indicated.

TREATMENT

General

Therapy for ExPEC infections depends on the site and severity of infection. The choice of antibiotics must be determined on the basis of local region antibiotic susceptibilities, site to which the antibiotic is to be delivered, and appropriateness and tolerance of oral or parenteral agents.

Urinary Tract Infection

Determination of therapy for UTI is first contingent on the appropriateness of oral therapy or intravenous antibiotics. Most community-acquired UTIs may be treated with oral therapy, assuming antibiotic resistance that would preclude therapy with an available oral agent is not suspected, the child is able to tolerate oral therapy (e.g., not vomiting), and the child does not have underlying urinary tract anomalies or other comorbidities such as diabetes mellitus, renal transplantation, systemic lupus erythematosus, or other conditions. Infants with UTI in the first month of life should be given parenteral antibiotics at the start of their treatment because of the challenge of clinically differentiating lower tract and upper tract infections, the high prevalence of concomitant bacteremia (~10%), and concurrent urinary tract pathology, including posterior urethral valves, obstructed duplex systems, and high-grade vesicoureteric reflux with serious metabolic disturbance, such as hyperkalemia and hypernatremia. Furthermore, past trials have excluded young infants, leaving no specific data to further guide management of UTI in this group.

The duration of therapy for cystitis should be 5 to 7 days, although pediatric-specific data regarding sufficient minimum duration of therapy are not available. Caution must be taken because it may be difficult in the young child to differentiate lower and upper urinary tract involvement, especially given that fever is a typical presenting symptom suggesting upper tract involvement. Typical therapy entails oral trimethoprim-sulfamethoxazole (TMP-SMX), trimethoprim alone, cephalexin, amoxicillin-clavulanate, or nitrofurantoin. The fluoroquinolone ciprofloxacin is not approved for use in children except for complicated *E. coli* UTI.

Prior research has indicated that oral therapy for pyelonephritis using the cephalosporins cefixime and ceftibuten or amoxicillin-clavulanate is effective in treating acute infections and does not result in a significant increase in renal scarring in contrast to initial parenteral therapy.[43,85,90] Pyelonephritis should be treated for a longer duration of 10 to 14 days. In children who are not candidates for initial oral therapy, 2 to 3 days of parenteral therapy should be provided until the child is able to tolerate an oral agent. However, no difference in renal scarring was identified in children receiving initial parenteral therapy before oral therapy in contrast to children receiving oral therapy for the entire course.[90] Longer initial intravenous therapy (8 days vs. 3 days) also was not shown to decrease renal scarring.[13] The combined duration of parenteral and oral therapy should then be the same as for children receiving only oral therapy.

E. coli UTI complicated by perinephric or intrarenal abscess may require surgical drainage and longer therapy. Ultrasound evaluation may be indicated before discontinuation of therapy.

The role of prophylactic antibiotics for the prevention of *E. coli* UTI has changed in recent years as more studies indicate they do not provide significant protection from recurrent infections[31,84,96,99] or in studies demonstrating protection from recurrent *E. coli* infection, prophylactic antibiotics, particularly cephalosporins, may result in subsequent infections with resistant organisms.[35,88] Exceptions may be for children with high-grade vesicoureteral reflux grades IV and V, in which data are currently insufficient to fully determine whether the benefits of daily antibiotic prophylaxis to prevent recurrent UTI and renal scarring outweigh the risks that include cost and the emergence of multidrug-resistant organisms. Trimethoprim-sulfamethoxazole or nitrofurantoin may be considered in these circumstances.

Other Infections

The treatment of invasive infections for *E. coli* should entail parenteral antibiotics of the appropriate spectrum, accounting for local resistance patterns and, in the case of empirical coverage, for other possible etiologic agents. Two antimicrobials with independent mechanisms of action such as a β-lactam and an aminoglycoside should be considered in patients at risk for multidrug-resistant *E. coli* infections. Past hospitalization and antibiotic exposure are among the risk factors for multidrug resistance.

The treatment of *E. coli* bloodstream infections is generally 10 to 14 days. Serious consideration should be given to the removal of central venous catheters in the presence of a high degree of suspicion that the catheter may be involved or responsible for the infection, although mixed data exist for the necessity of catheter removal.[6,16,38,97] *E. coli* meningitis should be treated for a minimum of 21 days or 14 days after obtaining a negative CSF culture, whichever is longer.[100] Parenteral therapy is indicated for both bloodstream infection and meningitis. Treatment of *E. coli* meningitis should include an agent with known penetration of the blood-brain barrier, for example, an advanced cephalosporin such as cefotaxime or a carbapenem such as meropenem, as well as an aminoglycoside, until full antibiotic susceptibilities are available.

Antibiotic Susceptibility

Specific antibiotic susceptibility data for pediatric *E. coli* isolates in North America is severely lacking. However, the antibiotic resistance of *E. coli* causing invasive infections among the population as a whole, particularly UTI, has undergone major shifts over the past decade. Previously *E. coli* was widely susceptible to a range of antibiotics, but in the past decade, resistance has increased in prevalence (see Table 103-4). Susceptibilities of *E. coli* to cephalexin and cefixime, often employed in treating pediatric *E. coli* infections in the outpatient setting, are notably unavailable. Antibiotic resistance to ampicillin, amoxicillin, and TMP-SMX is now broadly distributed. Neonates delivered to mothers treated with ampicillin for the prevention of group B streptococcus infection have an increased risk for ampicillin-resistant *E. coli* early-onset sepsis.[9] Furthermore, multidrug resistance is common. Of the *E. coli* resistant to TMP-SMX, they are 2 times more likely to be resistant to ampicillin and 33 times more likely to be resistant to the fluoroquinolones and nitrofurantoin.[138]

Risk factors associated with infection with extended-spectrum β-lactamase (ESBL)-producing *E. coli* include underlying illness and hospitalization in the previous 3 months.[127]

OUTCOMES

General

Outcomes of *E. coli* infections depend on the degree of invasiveness and status of the host immunologic defenses.

Urinary Tract Infection

Cystitis has the lowest morbidity, mostly incurred in terms of socioeconomic costs and emergence of antibiotic resistance. In contrast, pyelonephritis and other renal infections require more extended antibiotic therapy, incurring more cost and lost time from school and work. Furthermore, renal infections may result in progressive renal scarring with the concern for loss of renal function and early renal insufficiency. In some circumstances, particularly in young children, children with anatomic variations of the urinary tract and those with diabetes, UTI may precede bloodstream infections.

Other Infections

The mortality rate for early-onset and late-onset sepsis in neonates has been previously shown to be approximately 15 percent and 9 percent, respectively.[52] In infants with very low birth-weight (<1500 g) the odds ratio of death with early-onset and late-onset sepsis was 1.45 and 1.30, respectively, with *E. coli* contributing to this degree of risk.[46] Among older children with central venous catheter–related *E. coli* bloodstream infections, the mortality rate is approximately 7 percent despite appropriate antibiotic therapy, with parenteral nutrition and mechanical ventilation being predictors for poor outcome.[16]

In a 25-year retrospective study of neonates with meningitis in a tertiary medical center, of which *E. coli* was one of the top three pathogens, approximately 14 percent died and 40 percent had significant morbidity, including seizures and hearing loss.[74]

CHAPTER 104

Diarrhea-Causing and Dysentery-Causing *Escherichia coli*

Jorge J. Velarde • Andrea A. Berry • James P. Nataro

Escherichia coli has long been recognized as the most common facultative anaerobe in the human gastrointestinal tract. Virtually all *Homo sapiens* (and most other mammals) harbor this bacterium. Yet within the *E. coli* biomass lurk highly evolved pathogenic subtypes that have adapted themselves to a new niche—human pathogenicity. These pathotypes may prefer the gastrointestinal tract, the genitourinary tract, or disseminated sites (including the meninges)—the last almost exclusively in neonates. This chapter focuses on *E. coli* associated with enteric infections.

The first implication of *E. coli* with diarrhea occurred more than 75 years ago, when Adam[3] postulated the existence of a group of "dyspepsia" *E. coli* responsible for neonatal and infantile diarrhea. In the 1940s, Bray reported that many, but not all, *E. coli* from severe infant diarrhea cases in summer agglutinated with antiserum prepared from a diarrheal isolate, whereas *E. coli* organisms from other sources did not.[11] The isolate used by Bray to develop the antiserum was later serotyped by the Kauffman scheme as O111:B4, one of the now classic serogroups of enteropathogenic *E. coli* (EPEC) (Table 104-1). Although this initial description was made possible by serologic fingerprinting, the advent of molecular biology rapidly produced a plethora of reports describing the several discrete *E. coli* pathotypes.

CAUSATIVE ORGANISMS

Six distinct diarrheogenic pathotypes are recognized currently on the basis of clinical, biochemical, and molecular or genetic criteria (Table 104-2), as follows:

1. Enterotoxigenic *E. coli* (ETEC), a major cause of traveler's diarrhea and infant diarrhea in developing countries, elaborates the heat-stable enterotoxin, the heat-labile enterotoxin, or both and causes infection of the small intestine.
2. EPEC, the original pathotype defined by Bray,[11] causes infant diarrhea in less-developed countries. The bacteria induce a characteristic attaching and effacing lesion in the small intestine. Classic EPEC requires the chromosomally encoded locus of enterocyte effacement and a high-molecular-weight virulence plasmid termed EPEC adherence factor plasmid.
3. Enterohemorrhagic *E. coli* (EHEC) causes outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome in temperate climates. The essential virulence factor is the Shiga toxin, which circulates through the bloodstream and acts by inhibition of protein synthesis in the target cell.
4. Enteroinvasive *E. coli* (EIEC) is an unusual cause of diarrhea and dysentery. It is similar to *Shigella* epidemiologically and pathogenetically and shares similar virulence genes.
5. Enteroaggregative *E. coli* (EAEC) causes diarrhea in individuals of all ages in industrialized countries and in less-developed areas and in travelers. The organism adheres to the intestinal mucosa and secretes several enterotoxins and cytotoxins.[123]
6. Diffusely adherent *E. coli* (DAEC) is the sixth category. As a pathotype it is very heterogeneous, and its association with diarrhea is controversial. The epidemiologic scenario for this organism has not been well elucidated.

TRANSMISSION AND EPIDEMIOLOGY

Diarrheogenic *E. coli* strains are worldwide in distribution. The route of infection is fecal-oral, predominantly via contaminated food and water, although person-to-person transmission may occur with EHEC and possibly EPEC in infants.[150] As discussed subsequently, environmental contamination by EHEC is an emerging problem in industrialized countries, whereas ETEC continues to be ubiquitous worldwide. Table 104-3 lists the age-specific predilections of the various *E. coli* pathogens.

Enterotoxigenic *Escherichia coli*

The infectious dose for ETEC is approximately 10^8 bacteria.[59] The incubation period is 14 to 50 hours.[148] Transmission typically occurs via contamination of food and water,[203] and person-to-person transmission is thought to be uncommon because of its high infectious dose. In developing countries, contamination of food and water sources occurs commonly.[181] ETEC has additionally been detected in the United States in numerous food samples, including cheese, hamburger, sausage, and seafood.[101,137,203] A domestic U.S. outbreak of diarrhea at Crater Lake National Park in Oregon was traced to ETEC organisms in the water supply.[196] Because large numbers of organisms are required for experimental infection, transmission probably would require multiplication of the

inoculum within the vehicle, which probably contributes to the well-documented propensity of ETEC infection to occur in warm months.[181]

ETEC is a major cause of diarrhea in infants and children in the developing world.[78,181] The incidence typically increases during the first 6 months of life and decreases after 2 years. ETEC has been estimated to cause approximately 20 percent of diarrheal episodes in the developing world,[181] although this percentage varies substantially by location. A study in rural Egypt found that ETEC accounted for 66 percent of all first episodes of diarrhea, with an incidence of 1.7 episodes per child-year during the first 6 months of life and 2.3 during the second 6 months.[184] In Tehran, researchers found that ETEC could be isolated from 15.5 percent of patients younger than 5 years old with diarrhea. [206] The

prevalence was 18 percent in Bangladesh,[180] 33 to 37.5 percent in Mexico,[47,65] and 20.5 percent among children with diarrhea in Nicaragua.[254] A study in Hanoi found, however, that only 2.2 percent of diarrheal episodes could be attributed to ETEC.[158] Prevalence was 9.2 percent in a study in the Brazilian northeast,[160] and the frequency in Mongolia[209] was similarly low.

ETEC disease is primarily a childhood problem, with the incidence decreasing after the child reaches 5 years of age.[180,181] After infection with a particular ETEC strain, the host is resistant to disease but still may excrete the organism asymptomatically, a characteristic that contributes to the environmental burden.[150,233] Adults still may be susceptible to ETEC diarrhea.[78,181] In a study of elderly individuals in Dhaka, Bangladesh, researchers found that 13 percent of adults older than 60 years with diarrhea were noted to have ETEC.[66] Although the incidence of ETEC diarrhea decreases after age 5 years, the incidence seems to increase again in patients older than 15 years, and 25 percent of ETEC infections are seen in adults.[180,181]

ETEC is the most common cause of traveler's diarrhea, typically accounting for approximately 30 to 40 percent of cases, except in southeast Asia, where it has been found to account for approximately 7 percent of cases.[2,104,212,217] Illness is acquired by ingestion of contaminated food or water. The diarrhea is acute and watery and typically resolves spontaneously without severe limitation of activities.[2]

ETEC organisms are extremely diverse, and children in endemic areas experience multiple infections. The basis of immunity, which increases with repeated exposure, is unknown.[233] Strains producing heat-stable enterotoxin cause more severe disease than strains producing only heat-labile enterotoxin, and the former is not immunogenic. Colonization of the small intestinal mucosa is mediated by surface fimbriae termed *colonization factor antigens*, which are immunogenic and may elicit some element of protective immunity.[185] Despite the existence of more than 25 known colonization factor antigens, a few are overrepresented among clinical isolates[159,201,218,254]; in a study from Bangladesh for instance, seven colonization factor antigens constituted more than 75 percent of the colonization factor antigens isolated.[180] In an analysis of multiple studies, Wolf [260] suggested that most ETEC express colonization factor antigens I, II (CS1, CS2, CS3), or IV (CS4, CS5, CS6). In some epidemiologic studies, however, more than 50 percent of strains do not express known colonization factor antigens.[218,219] This may be secondary to the presence of colonization factor antigens that are as yet unrecognized.[147] ETEC is predominantly an infection of warm weather months in endemic areas, coincident with conditions promoting bacterial replication in the environment. Some sites report that a second peak occurs after the rainy season.[180,181]

Enteropathogenic *Escherichia coli*

Neter and associates[157] first coined the term *EPEC* to denote a group of *E. coli* serotypes associated with dramatic and highly lethal nursery outbreaks of diarrhea in the United States and the United Kingdom (see Table 104-1). We now recognize that these serotype antigens serve as surrogate markers for a package of chromosomal and plasmid-borne virulence genes, which together orchestrate enteric pathogenesis. The epidemiology of EPEC has changed since its original description was provided. Gone are the lethal outbreaks formerly reported in industrialized countries, to be replaced by sporadic endemic disease in resource-poor countries. The infection retains its dramatic predilection for infants and children younger than 24 months, is rarely seen in older children and adults, and is not a cause of traveler's diarrhea.[46,47,79,247] The basis of this age-dependent incidence is unknown.

Globally, EPEC is among the most common causes of infant diarrhea.* EPEC has a propensity to cause persistent infection and wasting, suggesting that its burden may comprise more than simple dehydration. Breast-feeding offers some protection against EPEC because of the presence of immune factors and oligosaccharides that inhibit adherence of EPEC to epithelial cells.[49] In industrialized countries such as the United States, EPEC generally is no longer considered to be a cause of endemic diarrhea, although EPEC may be present in infants immigrating from or visiting resource-poor settings. Rare indigenous cases may occur.[82] In an outpatient setting in the United States, 2 of 147 cases of nondysenteric acute diarrhea were caused by EPEC.[33] In 166 Swiss children admitted to hospitals with diarrhea, 13 (7.8%) had EPEC isolated from stool cultures.[64]

As noted previously, EPEC strains of the classic serotypes (also known as typical EPEC) require the chromosomal locus and the EPEC adherence factor plasmid to cause diarrhea. Controversy exists over whether so-called atypical EPEC (which are positive for locus of enterocyte effacement and negative for EPEC adherence factor) are a cause of diarrhea.[149] The description of an outbreak of diarrhea in Japan caused by an atypical EPEC strain suggests that at least some of these strains are pathogenic.[263] Recent molecular epidemiologic studies have suggested that atypical EPEC may require a chromosomally encoded adhesion factor termed *Efa1*,[4,163] which may substitute for the EPEC adherence factor plasmid-encoded bundle-forming pilus.

Enterohemorrhagic *Escherichia coli*

Since its discovery in 1977, EHEC has emerged as an important and increasingly common human pathogen. Although most occurrences of disease are sporadic and not all occurrences are related to ground beef,[243] EHEC is notably carried asymptomatically in cattle and other ruminants, from whence it can be transmitted widely. The organisms may be excreted by cattle herds, and large outbreaks of human infection have been associated with the ingestion of undercooked hamburger and other foods contaminated directly and indirectly by cattle manure. Careful prospective epidemiologic surveillance in Minnesota has revealed an increase in the incidence of EHEC from 0.5 to 2/100,000 children younger than 18 years of age during the period 1979 to 1988,[133] similar to the incidence of EHEC determined in the state of

*References 46, 47, 79, 163, 164, 191.

Washington in the late 1980s: 2.1/100,000. In a multicenter study of mild acute diarrhea in outpatients in the United States, 5 (3.4%) of 147 cases were caused by EHEC,[33] a frequency similar to that in Swiss children hospitalized for community-acquired diarrhea.[64] Very young children are not commonly infected; rather, infection occurs most commonly and severely in children 2 to 10 years old or in the elderly.

Ground beef is identified as the most common source of EHEC infection. Several outbreaks have been associated with fast-food consumption.[183] In meat-processing plants where bulk ground beef is prepared for the fast-food industry, meat from one contaminated carcass can contaminate and distribute the organisms to a huge number of beef patties. Several other food sources of transmission that have been documented include other beef; produce, including spinach and lettuce; milk; water; and processed foods, including unpasteurized apple cider, mayonnaise, and dry fermented sausage. Person-to-person, cattle-to-person, and waterborne outbreaks have been described. Person-to-person spread as sequelae of point-source epidemics is common.[216] Many unusual modes of transmission linked with cattle have occurred and include poorly washed apples dropped in cow pastures and used to make cider, surface water supplies in proximity to areas where cattle graze, spread of aerosolized particles at agricultural fairs, and transmission by contact at petting zoos. Contaminated swimming holes have been implicated in several outbreaks.

A multistate outbreak of O157:H7 EHEC infections associated with the consumption of fresh bagged spinach occurred in the United States in 2006, affecting 26 states and resulting in 205 confirmed illnesses, 103 hospitalizations, 31 cases of hemolytic-uremic syndrome, and 3 deaths.[13,34] This outbreak exemplifies the widespread effect of a foodborne outbreak caused by the mass production and distribution of produce.

Hemolytic-uremic syndrome is a not-infrequent sequelae of EHEC-associated infection. A review of O157:H7 outbreaks (defined as two or more cases) reported to the Centers for Disease Control and Prevention (CDC) in the United States from 1982 to 2002 found 350 outbreaks, representing 8598 cases, 1493 (17%) hospitalizations, 354 (4%) cases of hemolytic-uremic syndrome, and 40 (0.5%) deaths.[183] During a large outbreak of *E. coli* O157:H7 infection associated with fast-food restaurant hamburgers on the West Coast of the United States in 1993, of the 732 affected individuals identified, 195 were admitted to the hospital, hemolytic-uremic syndrome developed in 55 (7.5%), and 4 died.[82] Investigation of this outbreak showed that small numbers of bacteria (in the range of a few hundred) constituted an infectious dose. Among 93 cases of O157:H7 infection reported in Washington State in 1987, hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura developed in 11 (12%), for an approximate incidence of 0.23 per 100,000.[171]

The highest incidence of hemolytic-uremic syndrome occurs in children younger than 5 years, in whom the age-specific incidence ranged from 2.6 to 5.8/100,000 in Minnesota,[133] Washington,[171] and Oregon.[194] More recently, improvements in animal processing and public health interventions, including detection and investigation of outbreaks, has led to a U.S. national decrease in the incidence of hemolytic-uremic syndrome to fewer than 1 case/100,000.[38] The incidence of hemolytic-uremic syndrome in Argentina, 21.7/100,000, is four to eight times higher and is the highest reported incidence of hemolytic-uremic syndrome in the world.[129]

In the United Kingdom and the United States, hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura are associated predominantly with Shiga toxin 2–producing *E. coli* O157:H7[133,172]; however, this finding may represent more facile detection of this serotype. In addition, the incidence of non-O157:H7 infections in the United States is increasing (serotypes associated with EHEC infection are presented in Table 104-1).[31,106,259] In Argentina, non-O157:H7, Shiga toxin 2–producing strains are isolated most commonly.[129] Similarly, in Australia, other serotypes, especially O111, have been associated with major outbreaks and a significant number of hemolytic-uremic syndrome cases.[36] Many of these serotypes have been implicated in sporadic and outbreak disease in the United States[30] (e.g., an outbreak caused by O104:H21 acquired from contaminated milk).[37]

Non-O157:H7 EHEC infections have increased in prevalence in the United States and are now known to account for 20 to 50 percent of all EHEC infections.[106] Although some non-O157 strains are not pathogenic, others have been shown to cause disease as severe as that caused by O157:H7 strains, suggesting that a clinical suspicion for EHEC should be maintained even when testing for O157:H7 is negative.[106] Non-O157, Shiga toxin 2–producing *E. coli* infection was made a reportable disease in the United States in 2000.[31]

Hemolytic-uremic syndrome occurs seasonally in the United States and Canada (most common during the summer months), although no specific seasonal risk factor or factors for infection with Shiga toxin–producing *E. coli* are known. Other epidemiologic data suggest that poor children are at lower risk for the development of hemolytic-uremic syndrome, perhaps because they already have immunity to EHEC or Shiga toxins through early contact with the organisms in their environment.[42]

Enteroinvasive *Escherichia coli*

EIEC is closely related to *Shigella* microbiologically and pathogenetically. The pathotype typically is found in areas with a high burden of *Shigella*. The infectious dose may be higher than that of *Shigella*, and person-to-person transmission seldom is reported. Food-borne outbreaks occur sporadically.[80,132] The first description of EIEC as a pathotype occurred in 1971, when bloody diarrhea was traced to the consumption of French Camembert cheese contaminated with *E. coli* O124.[132] Small outbreaks or sporadic cases involving a limited number of serotypes have been reported from numerous countries, including the United States, France, Japan, and Brazil.[132,165,227,248,251] The prevalence varies by region. In a rural community in Ecuador up to 20.5 percent of diarrheal cases were due to EIEC[200]; in Tunisia 11.3 percent of children with diarrhea had EIEC.[8] Prospective studies in Thailand using DNA probes for EIEC pathogenicity genes indicated that 6 percent of cases of dysentery may be caused by

EIEC strains.[60] Similarly, studies in Nicaragua, South India, Vietnam, Gabon, Tanzania, Denmark, and multiple sites in Africa, including Kenya, Ghana, and Nigeria, demonstrated low to nondetectable rates of EIEC.* The epidemiology of the cases is complicated by the fact that in contrast to the initial descriptions of EIEC-associated disease, most EIEC infections probably are neither dysenteric nor characterized by bloody diarrhea but instead manifest as watery diarrhea with low-grade fever, similar to that caused by viral agents and ETEC.

Infection with 10^8 bacteria has been shown to be necessary for experimental dysentery in human volunteers,[59] a dose substantially higher than that for *Shigella* spp. ($\leq 10^4$ organisms). In a food-borne outbreak caused by a nontypeable EIEC, secondary person-to-person transmission was not reported.[227]

Enteroaggregative *Escherichia coli*

EAEC was implicated first as a cause of diarrheal disease in studies of children in Chile, Mexico, and India.[23,24,48,153] The pathogenicity of at least some EAEC strains has been established by several observations. First, volunteer studies by Nataro and associates[152] revealed that some EAEC could elicit diarrhea in healthy subjects, whereas other strains may not be pathogenic. Second, EAEC strains have been implicated in outbreaks of diarrhea, the largest of which involved nearly 2700 schoolchildren in Japan.[88,100,264] Finally, but most emphatically, a meta-analysis performed by Huang and colleagues[97] of more than 20 years of studies revealed convincingly that EAEC is a cause of diarrhea in infants; adults, especially those with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) in developing countries; children in industrialized countries; and adult travelers to less-developed areas. In addition, a study from the United States by Nataro and colleagues[154] suggested that EAEC was the most frequent bacterial cause of diarrhea among all ages in Baltimore, Maryland, and New Haven, Connecticut.

A persisting controversy surrounding EAEC epidemiology and pathogenesis is the definition of the pathotype. The meta-analysis described earlier implicated EAEC, as defined by the characteristic stacked-brick adherence pattern to epithelial cells in culture.[97] A study of infant diarrhea in Cincinnati suggested, however, that only strains hybridizing with an EAEC gene probe (see later discussion) were truly associated with clinical diarrhea.[44] A full understanding of what constitutes a truly pathogenic EAEC strain is unavailable.

Diffusely Adherent *Escherichia coli*

The association between DAEC and diarrhea remains controversial. When DAEC was given to adult volunteers, it failed to convincingly elicit symptoms.[239] Additionally, this strain has been found in both healthy individuals and patients with diarrhea.[166,215] An age-related association may exist in children older than 12 to 18 months.[150,168,211,232] Of note, the commonly used *daaC* probe has been found to cross react with some strains of EAEC, which may have led to overestimation of DAEC in some studies.[226] Finally, DuPont and colleagues[140] suggest that DAEC may also play a role in traveler's diarrhea previously identified as pathogen negative.

*References 94, 146, 166, 167, 182, 188, 207.

CLINICAL MANIFESTATIONS

Diarrhea-causing *E. coli* may be responsible for a variety of clinical syndromes because virtually all known mechanisms of diarrhea, including secretory toxins, cytotoxic toxins, invasion, and pathogenic adherence, are manifested by the various *E. coli* pathotypes. The clinical manifestations are largely a function of the complement of virulence genes (see Table 104-2), and identification of the essential pathogenicity genes provides the definitive diagnostic maneuver. As with other pathogens, invasive *E. coli* strains (i.e., EIEC) produce inflammatory diarrhea with fever, abdominal pain, nausea, vomiting, and leukocytes and blood in the stool. Noninvasive, cytotoxin-producing EHEC strains cause a frankly bloody diarrhea associated with leukocytosis but without fecal leukocytes or fever. Producers of heat-stable or heat-labile enterotoxins (i.e., ETEC) elicit brisk, watery diarrhea with the potential for significant dehydration.

Enterotoxigenic *Escherichia coli*

ETEC causes watery, nonmucoid, nonbloody diarrhea in infants, older children, and adults, and it is a common cause of traveler's diarrhea.[181] The onset of diarrhea is abrupt, with an incubation period of 14 to 50 hours.[148] The frequency of stools varies from a few to more than 10 per day, and a striking absence of leukocytes is noted when the diarrheal stool is examined by light microscopy. Young affected children may vomit and commonly are febrile (38° to 40° C [100.4° to 104° F]), although adults typically are afebrile. ETEC disease cannot be distinguished clinically from most other causes of acute nonspecific watery diarrhea. The illness usually is self-limited to 3 to 5 days but occasionally lasts more than 1 week. Severely dehydrating illness that resembles clinical cholera can occur but is uncommon.

Variability in the clinical picture may be due to age differences and preexisting immunity, but it also may be attributed to differences in the infecting inoculum. DuPont and colleagues[58] produced mild diarrhea (three watery stools per day for 2 to 3 days) when 10^8 bacteria were fed to adult volunteers, whereas 10^{10} organisms caused more pronounced diarrhea (more than five stools per day for 4 to 5 days), with mucus but no blood observed in some subjects. Many subjects also had abdominal cramping, but no tenesmus was present, and all remained afebrile. This clinical picture is typical of traveler's diarrhea in adults.[142] ETEC diarrhea can result in severe dehydration necessitating aggressive fluid therapy.

Enteropathogenic *Escherichia coli*

EPEC diarrhea typically is copious and watery, without blood or fecal leukocytes.[124] Patients may have low-grade fever. In a Swiss study conducted with modern diagnostic methods, the mean age of 13 hospitalized children with

EPEC diarrhea was 1.4 years (range, 0.5 to 3 years).[64] Fever was low-grade, and vomiting occurred in 69 percent. Volume depletion was considered moderate in five children and severe in two. Although nursery outbreaks no longer occur commonly, severe illness still can develop in infants infected with EPEC,[103] with high mortality rates ranging from 25 to 70 percent.[53] The cause of death of patients in nursery outbreaks is not well documented. Investigations using an experimental EPEC infection model in adult volunteers (who are not naturally susceptible) revealed that watery diarrhea occurred 3 to 16 hours after inoculation and generally lasted less than 2 days. Diarrhea occasionally was copious and in some cases was associated with abdominal cramps, nausea, vomiting, malaise, and fever.[56] This clinical picture is consistent with disease caused by outbreaks of EPEC in adults.

EPEC also has been implicated in chronic diarrhea in the United States and elsewhere, with serious nutritional consequences that may require total parenteral nutrition and hospital stays of 120 days.[197] In prospective studies of EPEC diarrhea in young infants in Brazil[79] and Ethiopia,[246] fever, vomiting, and dehydration all were observed commonly. The clinical significance of chronic diarrhea may be increased by the underlying malnutrition of infants in resource-poor countries. In many settings, especially where effective oral rehydration programs are in place, chronic diarrhea and associated malnutrition are now more important causes of diarrheal deaths than are acute diarrhea and dehydration.[28]

In the course of the classic, severe nursery outbreaks caused by typical EPEC strains, the first signs and symptoms were mild and nonspecific, but they commonly were followed by vomiting and diarrhea of increasing severity. Stools contained neither mucus nor blood, and the volume fluctuated over a period of weeks. Plain abdominal radiographs revealed only nonspecific dilation of small bowel loops, although severe ileus not attributable to hypokalemia developed in many patients. Infected infants lost as much as 15 percent of body weight, leading to profound electrolyte disturbances and severe dehydration, along with central nervous system manifestations, such as irritability, hypertonicity, seizures, and coma. Circulatory collapse occurred despite adequate replacement of fluids and achievement of electrolyte balance. In an epidemic in Virginia, Belnap and O'Donnell[19] described fatal infections caused by *E. coli* O111:B4 occurring after 3 weeks of illness and associated with renal failure, coma, and signs of disseminated intravascular coagulation, but blood cultures typically remained negative. The fatality rate was age-dependent; although the overall mortality was 16 percent, the rate in neonates was 40 percent.

Enterohemorrhagic *Escherichia coli*

In 1971, a distinctive clinical diarrheal syndrome was recognized that was characterized by afebrile bloody diarrhea in addition to cramping and colonic inflammatory changes, usually right-sided.[189] In 1983, this illness was associated with an otherwise rare *E. coli* serotype, O157:H7, and a characteristic syndrome, hemorrhagic colitis, was defined.[190] O157:H7 subsequently was recognized as the most virulent prototype of a Shiga toxin–producing pathotype designated EHEC. EHEC now has been shown to cause a wide spectrum of diseases that may be confined to the gastrointestinal tract or, in a sizable proportion (typically 5% to 10%), can become systemic.[18,243] After an incubation period of 3 to 4 days (range, 1 to 8 days), the local gastrointestinal illness usually begins with nonbloody diarrhea that can progress to bloody diarrhea after 1 or 2 days. Hemorrhagic colitis occurs in 50 to 90 percent of O157:H7 infections.[171,243]

Further progression may occur over the course of the next day or two and result in the passage of frank blood, the pathognomonic clinical feature of hemorrhagic colitis. Associated manifestations include vomiting in approximately 50 percent of patients and abdominal pain. Fever may occur but typically is low-grade. This clinical picture may be confused with other conditions, such as appendicitis, intussusception, inflammatory bowel disease, ischemic colitis, and diverticulitis. The difficulty in establishing the diagnosis can lead to inappropriate drug therapy or even surgery.[82,98]

A serious complication of hemorrhagic colitis is the development of hemolytic-uremic syndrome.[82] Hemolytic-uremic syndrome is characterized by the triad of acute renal failure, thrombocytopenia, and hemolytic anemia and develops in approximately 10 to 20 percent of infected children younger than 10 years.[150] It is the most common cause of acquired renal failure in the United States.[249,250] The acute mortality rate is approximately 5 percent, and renal failure is expected to develop eventually in many more patients during the next several decades. After renal failure, cerebrovascular accident and colonic perforation are the most common serious sequelae. Thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome have some overlapping clinical and pathologic features, but thrombotic thrombocytopenic purpura is increasingly regarded as a separate clinical entity that is not associated with an antecedent EHEC infection[242]; the separation is supported by its separate pathophysiology (see later discussion).

A prospective study in Canada identified *E. coli* O157:H7 in 15 percent of 125 patients with grossly bloody diarrhea over a 6-month period.[173] The age range was 15 months to 73 years; however, almost half of the patients were younger than 10 years of age. The illness was similar to that described earlier, with a mean duration of 7.8 days, but it was significantly longer in children (9.1 ± 2 days) than in adults (6.6 ± 1.1 days). Sigmoidoscopy findings were abnormal in 7/8 adults examined, with hyperemic mucosa in 6 and superficial ulcerations in 1. Biopsy samples showed mild mucosal inflammation in 4/5 patients. In another study, the findings on colonoscopy in 10 patients with hemorrhagic colitis caused by *E. coli* O157:H7 included severe inflammation (predominantly right-sided), marked edema, easy hemorrhage, and the frequent appearance of longitudinal ulcerlike lesions.[221]

Because local and systemic manifestations in EHEC infection are caused, at least partially, by Shiga toxins, the presence of these same toxins in the intestinal lumen in patients with non-O157:H7 infection puts them at risk for development of hemorrhagic colitis and hemolytic-uremic syndrome. Available longitudinal data suggest

that O157:H7 infection results in more bloody diarrhea, hospitalization, and hemolytic-uremic syndrome than non-O157:H7 EHEC infection.[87,91]

Enteroinvasive *Escherichia coli*

Naturally acquired EIEC infection causes a mild to moderately severe dysentery syndrome consisting of fever, malaise, diarrhea, tenesmus, and abdominal cramping.[59,251] Watery diarrhea usually occurs at the onset of the illness and progresses to mucoid diarrhea with streaks of blood or microscopic hematochezia but rarely to the classic small-volume, grossly bloody, dysenteric stool seen with *Shigella* infection. Of 229 cases reported in one study, grossly bloody stool occurred in only 4.[132] In two of these patients, sigmoidoscopy revealed superficial ulcerations in one and hyperemia alone in the second patient. As in *Shigella* infection, the stool reveals abundant polymorphonuclear cells, compatible with the inflammatory, invasive nature of the organism. Vomiting and dehydration can occur; the latter generally is mild. Fever of 38° to 39.5°C (1040.4° to 103.1°F) is a typical symptom that occurs early in association with malaise, myalgia, and headache and lasts for 2 to 3 days. In most instances, the diarrhea ceases in 1 week or less, but in some patients, it may continue for 2 weeks or more.

In adult volunteers with experimentally induced EIEC disease, febrile illness developed approximately 11 hours (range, 8 to 24 hours) after the inoculum was ingested.[59] Chills, myalgia, headache, and profuse diarrhea or abdominal cramps and tenesmus rapidly followed. In 2/13 subjects, this picture was associated with systemic toxicity and transient hypotension consistent with bacteremia, even though blood cultures were negative for all patients. Clinical dysentery with bloody stools occurred in several subjects, and reddened, friable mucosa with multiple bleeding points was seen by sigmoidoscopy. Clinical illness was controlled quickly with parenteral ampicillin therapy.

Enteroaggregative *Escherichia coli*

Descriptions of EAEC clinical features are derived from outbreak investigations, volunteer studies, and studies of traveler's diarrhea.[97] Most EAEC infections are accompanied by watery diarrhea, which may progress to persistent diarrhea that lasts 14 days or longer.[24,150,153] Bloody diarrhea is observed in a subset of patients.[48] An EAEC strain was implicated in a school lunch outbreak in Tajimi City, Japan, in 1993.[100] Of 6636 children who ate the school lunch at 16 schools, 2697 (rate of attack 40.6%) reported gastrointestinal symptoms. Major symptoms were abdominal pain (73.6%), nausea (51.1%), and diarrhea (39.9%). The incubation period for the onset of gastrointestinal illness was 40 to 50 hours on average. Duration of symptoms was not reported. A nursery outbreak in Serbia involved 19 normal infants.[43] All experienced watery diarrhea, which persisted beyond 2 weeks in 3 patients. A report of 17 pediatric patients with illness caused by EAEC of serotype O126:H27 in Israel suggested that patients typically manifested diarrhea (in all), vomiting (in 8), and fever (in 12, ≤40°C [104°F]).[220] In this report, one 6-week-old infant developed diarrhea persisting for 40 days. Studies in travelers suggest that EAEC disease may be mildly inflammatory, although fever and fecal leukocytes are present in a few patients.[97]

The particularly severe epidemic linked to an O104:H4 Shiga toxin–producing EAEC strain[187] differed from O157:H7-induced disease in several ways. Sequelae were more severe in adults than children, and overall the frequency of hemolytic-uremic syndrome and death was unusually high. Diarrhea in patients infected with O104:H4 was similar to that described in patients infected with O157:H7, suggesting that presentation of Shiga toxin at the site of infection does not require a set of virulence factors unique to EHEC strains.

Diffusely Adherent *Escherichia coli*

The association between DAEC and diarrhea remains controversial. Typically in cases in which a relationship is thought to exist, it causes a watery diarrhea that can be prolonged.[150]

PATHOGENESIS

Enterotoxigenic *Escherichia coli*

ETEC was identified first as a porcine pathogen,[86,224] which elicited fluid secretion when injected into ligated ileal loops.[86] Two secretogenic activities were characterized; one could be inactivated by heating and the other could not, and the activities could be found both in the same strain or independently. These activities now have been assigned to two well-characterized enterotoxins, heat-stable and heat labile. Heat-labile enterotoxin is genetically, structurally, and mechanistically similar to the cholera toxin produced by *Vibrio cholerae* O1 strains.[76,150] Heat-stable enterotoxin is actually two distinct toxins: STa (including closely related STI peptides STI-a and STI-b) is associated with human disease, whereas STb causes disease only in animals.[70,150]

The essential pathogenic strategy for ETEC involves colonization of the proximal small intestine, followed by release of one or both of the enterotoxins. Colonization of the intestinal epithelium (Fig. 104-1) is likely initially mediated by the ETEC flagella aided by the tip adhesin, EtpA, that has been recently described.[198,199] It then becomes dependent on proteinaceous, hairlike bacterial surface appendages termed *fimbriae* (or *pili*), of which more than 25 antigenic types are known to exist.[147,260] These adherence factors are termed *colonization factor antigens* or *coli surface antigens* (Fig. 104-2).[74]

Human STa is a small, nonimmunogenic molecule that is translated as a 72–amino acid polypeptide.[228] The first 19 amino acids serve as a signal sequence for secretion into the periplasmic space; a further cleavage event occurs after secretion, which results in the final 18 (ST-Ia) to 19 (ST-Ib) amino acid active peptide.[70,150,186] The sequence of the mature heat-stabile enterotoxin has six cysteine residues that form stabilizing disulfide bonds, contributing to the high stability of the toxin to heat and proteases.[265] The heat-stable enterotoxin receptor

on the apical surface of the intestinal epithelial cells is guanylyl cyclase C. This receptor is a large transmembrane protein with an extracellular ligand-binding domain and intracellular catalytic domain; binding to guanylyl cyclase C results in its activation, which is responsible for an increase in cellular cyclic guanosine monophosphate (cGMP).[213] cGMP is an intracellular signaling molecule that induces activation of apical chloride channels and inhibition of absorptive mechanisms, contributing to a secretory diarrhea.[69,83,143] Heat-stabile enterotoxin exploits an endogenous signaling pathway, the natural agonist of which is the peptide guanylin, a natural controller of electrolyte homeostasis.[50]

The heat-labile family of toxins includes LT-I, which has significant homology in structure and function with cholera toxin, and LT-II, which does not seem to cause human or animal disease.[150] LT-I shares 80 percent identity with cholera toxin and similarly has an A_1-B_5 stoichiometry.[77,141,150,223,235] The 28-kDa A subunit is the catalytically active moiety, whereas the 11-kDa B subunit pentamer mediates cell binding and entry. Heat-labile enterotoxin interacts with G_{M1} gangliosides on the surface of the epithelial cells.[70,122,150] The A subunit is composed of two domains, A1 and A2, which are bound via a disulfide bond. A1 has an adenosine diphosphate–ribosyl transferase, which targets the cellular guanosine triphosphate binding protein $G_{s\alpha}$, a regulator of cellular cyclic adenosine monophosphate (cAMP) levels. Ribosylation of $G_{s\alpha}$ leads to constitutive activation of adenylate cyclase, which greatly increases cAMP levels.[70,214] Increased cAMP leads to increased phosphorylation of chloride channels, especially cystic fibrosis transmembrane conductance regulator (CFTR), by protein kinase A, and increased chloride secretion, which also may contribute to secretory diarrhea.[70,214] Heat-labile enterotoxin additionally seems to promote *E. coli* adherence to epithelial cells, a function dependent on ADP-ribosylation, although the mechanism remains unclear.[105]

Enteropathogenic *Escherichia coli*

EPEC pathogenesis is complex and only partly understood. In contrast to ETEC, it possesses no potent secretogenic toxin but rather induces changes to the enterocyte signal transduction environment, which transforms the enterocyte from an absorptive cell to a secretory cell. EPEC pathogenesis has been described as a multistep process. The first step comprises attachment to the small bowel mucosa, an event mediated by the EPEC adherence factor plasmid-encoded bundle-forming pilus. The bundle-forming pilus is a complex surface fimbrial structure that may undergo contraction, not only tethering the bacteria to the cell but also pulling itself close to the cell's apical membrane.[117] Approach of the bacteria is followed by induction of a characteristic lesion, termed *attaching and effacing*. Under electron microscopy, the normal microvillus architecture is dissolved, and the bacterium adheres tightly (<20 nm distance) to the now undulating membrane. The bacteria may be observed sitting atop a cup or pedestal of protruding cell membrane (Fig. 104-3). This deceptively simple phenotype is mediated and accompanied by a dizzying array of invisible changes to the cell's internal environment.[53]

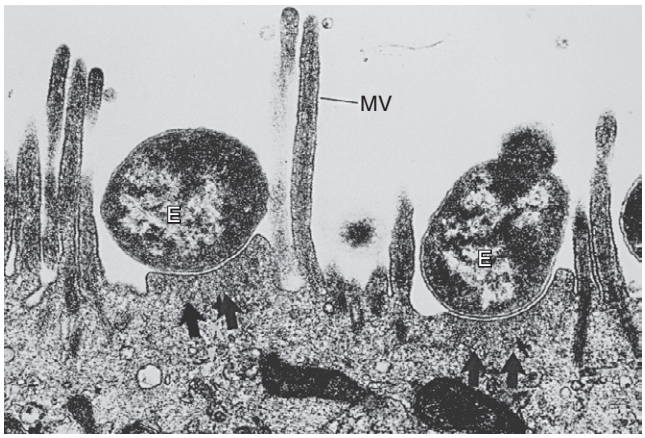

FIGURE 104-3 ■ High-power electron micrograph of intestinal epithelium infected by typical enteropathogenic *Escherichia coli* strains *(E),* with occasional intact microvilli *(MV)* and pedestal formation indicated by *double arrows.* This figure shows not only the structural alterations and loss of the brush border but also the close apposition of the organisms to the epithelial cells. (Courtesy Ralph A. Gianella, Department of Medicine, University of Cincinnati School of Medicine.)

Cellular changes are induced largely by a platoon of protein toxins that the bacterium injects directly into the cytoplasm of the target host cell. This injection process is mediated by a complex bacterial organelle termed an *injectisome*, also known as a *type III secretion system*. The first toxin injected is referred to as the *translocated intimin receptor* (Tir). Tir inserts itself into the apical plasma membrane, where it serves as the receptor for the bacterial outer membrane adhesion protein, *intimin*. As its name suggests, intimin mediates very close attachment of the bacterium to the cell and contributes to the resulting cytoskeletal damage.[39]

The net effect of Tir, intimin, and other injected toxins is dissolution of the microfilament and microtubule networks, phosphorylation of membrane ion transporters, and disruption of tight junctions at the cell's periphery. Diarrhea apparently is caused by a combination of ion transport and paracellular leakage.[258] Release of proinflammatory cytokines may complete the pathogenic cascade. The relative contributions of each of these events to EPEC disease are unknown.[39]

EPEC adhere to HEp-2 epithelial cells in a characteristic localized pattern, which has been suggested as a diagnostic assay (Fig. 104-4).[53] Also, EPEC causes actin polymerization of target cells at sites of attachment, a virulence property readily detected in tissue culture (e.g., HEp-2 cells) by a fluorescent actin-staining test (Fig. 104-5).[116] As discussed subsequently, these phenotypic assays, although useful for pathogenesis studies, have largely been replaced by molecular diagnostic tests.

Enterohemorrhagic *Escherichia coli*

The cardinal pathogenic feature of the EHEC pathotype is the production of Shiga toxin, accompanied by a cohort of accessory virulence factors. As with EPEC, these

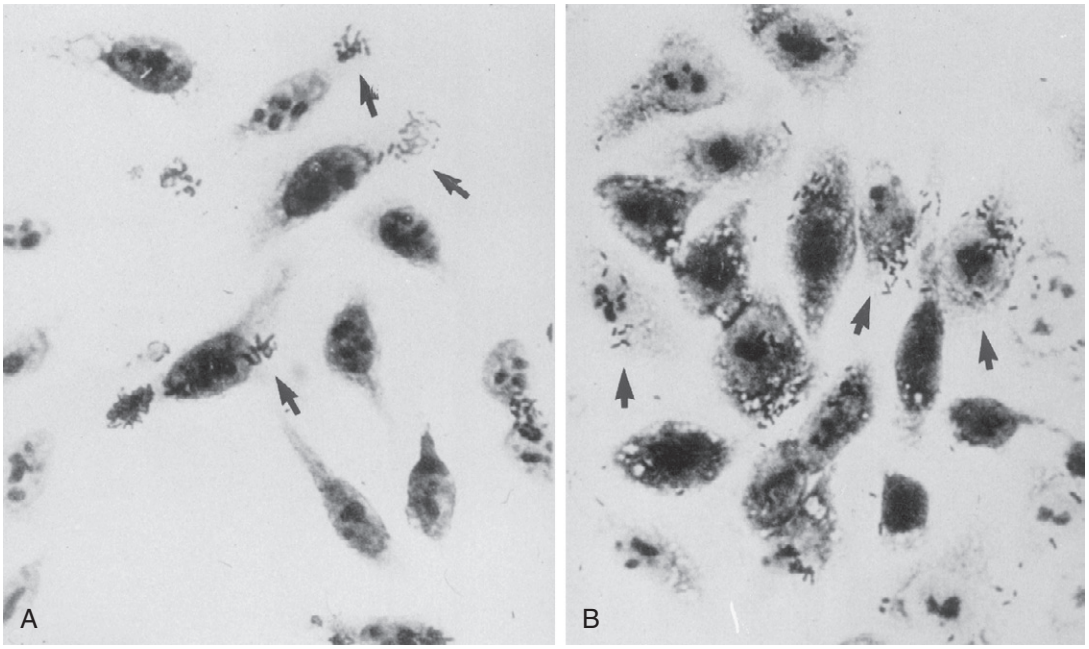

FIGURE 104-4 ■ Patterns of adherence of *Escherichia coli* to HEp-2 cells in tissue culture. Typical enteropathogenic *E. coli* associates with HEp-2 cells in the pattern shown in **A,** termed localized adherence (LA). *Arrows* point to cells where growing microcolonies of bacteria are attached to focal areas of the cell membrane. Other *E. coli* organisms isolated from patients with diarrhea adhere over the entire HEp-2 cell membrane, as shown in the cells identified with *arrows* in **B.** This pattern of interaction is termed diffuse adherence (DA). Although the LA phenotype has been associated definitively with the capacity to induce diarrhea in experimental models, evidence of virulence in DA strains remains controversial.

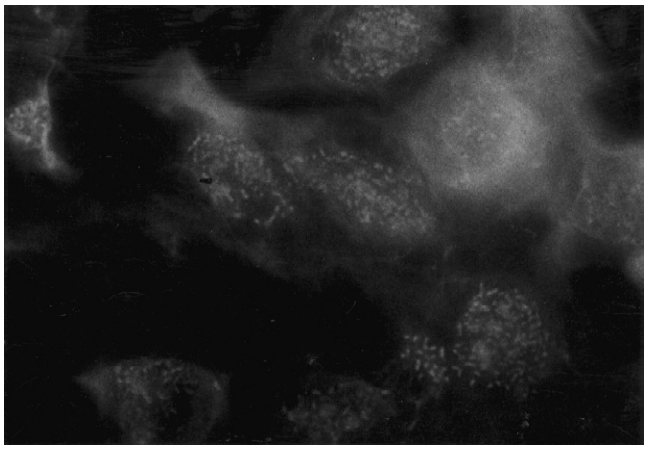

FIGURE 104-5 ■ Some *Escherichia coli* strains have the capacity to attach to the eukaryotic cell membrane and induce polymerization of actin beneath the membrane. This property may be shown by the fluorescent actin staining test, in which polymerized F-actin is detected by a fluorescein-tagged mushroom toxin specific for this form of actin. In this figure, the bacteria are attached to HEp-2 cells, and the induced actin polymerization revealed by the fluorescent reagent highlights the organisms, which are seen as bright rods on the infected cells.

factors are encoded by the bacterial chromosome and a high-molecular-weight virulence plasmid. Shiga toxin is encoded on a lysogenic phage, which is capable of infecting some non-EHEC *E. coli* strains. The full package of virulence genes has been well characterized in serotype O157:H7; studies that characterize locally obtained EHEC strains suggest that non-O157 pathogens are a heterogeneous group and tend to share some, but not all, of the virulence traits, accounting for their reduced virulence and frequency.[17,109,131] Shiga toxins were discovered by Konowalchuk and associates,[118] who reported finding Vero cell toxic activity in culture filtrates of certain strains of *E. coli* isolated from patients with diarrhea (Shiga toxin occasionally has been referred to by the archaic synonym *Vero toxin*).

Shiga toxins constitute a family of protein toxins that share identical enzymatic action and target cell binding specificity. Shiga toxins are subdivided into two families, Stx1 and Stx2, each consisting of the major Stx type and variants (i.e., Stx1c, Stx1d, Stx2c, Stx2c2, $Stx2d_{EH250}$, $Stx2d_{activatable}$, Stx2e, and Stx2f).[26] Stx2 and Stx2c have been associated with severe disease, including hemorrhagic colitis and hemolytic-uremic syndrome.[73,172] $Stx2d_{activatable}$ can be activated by mouse and human intestinal mucus and is associated with a severe clinical phenotype.[26] The greater pathogenicity of Shiga toxin 2 may be due to greater accessibility of the active site on the Shiga toxin 2 structure.[71] The *stx1* gene differs from the *Shigella stx* gene by three nucleotide changes, which result in a single conservative amino acid substitution in the A subunit: threonine to serine.[95]

Shiga toxins have the same structure and mechanism of action. They have an A_1-B_5 stoichiometry, comprising a single enzymatically active A subunit and a pentamer of B subunits responsible for toxin binding. The B subunits bind to globotrioacyl ceramide (Gb_3) and related glycolipids on host cells, including epithelial enterocytes, vascular endothelial cells, smooth muscle cells, renal endothelial cells, and erythrocytes.[54,120] The catalytic A subunit cleaves the *N*-glycosidic bond in a specific adenosine of the 28S rRNA in the 60S ribosomal subunit.[61] This single cleavage event results in irreversible cessation of protein synthesis and ultimately leads to cell death via

multiple signal transduction pathways.[45] Intestinal villus cells are susceptible to the action of Shiga toxin, which includes reduced absorption of sodium. Data suggest that Shiga toxin induces local inflammatory cytokine production, with potential effects on epithelial cell and mucosal integrity. This host response may induce a vicious cycle because both hydrogen peroxide and neutrophils augment production of Shiga toxins.[257]

Epidemiologic evidence strongly links Shiga toxin–producing strains to hemorrhagic colitis and to the associated systemic complications of hemolytic-uremic syndrome.[81,111,189] The mechanisms underlying hemolytic-uremic syndrome are unclear but seem to be due to the effects of toxin on vascular endothelial cells, possibly in concert with lipopolysaccharide and a variety of cytokines, which initiate events resulting in endothelial cell injury and platelet thrombi and, subsequently, the characteristic thrombotic microangiopathy.[42,112,162] Shiga toxin also activates complement and binds factor H, a complement regulator, leading to excess complement activation and deposition.[169] Other possible initiation factors include abnormal levels of von Willebrand factor, but whether this abnormality is a cause or a consequence of disease is unknown.[144] Shiga toxin 1 has been shown to decrease production of prostacyclins; however, the role of this event in the pathogenesis of hemolytic-uremic syndrome is unclear.[112] By contrast, thrombotic thrombocytopenic purpura results from autoantibodies against or mutations in the von Willebrand factor metalloprotease ADAMTS13.[242]

Similar to EPEC, EHEC express the intimin outer membrane protein and a type III secretion apparatus.[150] EHEC are capable of inducing complex cytoskeletal alterations similar to those caused by EPEC infection, although certain subtle differences are observed. EHEC infects the human colon, whereas EPEC is an infection of the small bowel. The genes encoding intimin, Tir, the type III secretion system, and secreted proteins reside on a 35-kb pathogenicity island called the locus of enterocyte effacement, which may be more crucial for EPEC than for EHEC for virulence.[54] A 60-Md plasmid, pO157, which contains genes encoding an enterohemolysin, is commonly found in O157:H7 strains, but its role in production of disease is unclear.[150] Subtilase cytotoxin (SubAB), a novel cytotoxin with an A_1-B_5 stoichiometry, is associated with hemolytic-uremic syndrome in diverse EHEC strains in Australia and the United States.[114,176] SubAB is heat-stable, more toxic to Vero cells than Shiga toxin, and lethal when injected in mice.[114,176] Cytotoxicity is the result of direct cleavage of an endoplasmic reticulum chaperone protein, BiP.[175]

Enteroinvasive *Escherichia coli*

In 1967, Trabulsi and coworkers[248] in Brazil and Sakazaki and associates[205] in Japan described the isolation of certain *E. coli* serotypes from patients with a disease resembling bacillary dysentery, but with cultures negative for *Shigella*. These isolates possessed a critical virulence hallmark associated with *Shigella*—the ability to invade intestinal and other epithelial cells (Fig. 104-6).[162] They have been referred to as EIEC, and a limited number of serotypes, distinct from the EPEC O groups, but often cross reactive with *Shigella* O antigens, have been found to possess this property (see Table 104-1). The genetic and molecular basis of invasion by *Shigella* was well defined in the 1990s, and the same plasmid and chromosomal genes encoding invasion properties and mechanisms seem to be present in EIEC as well.[96,125,174,208]

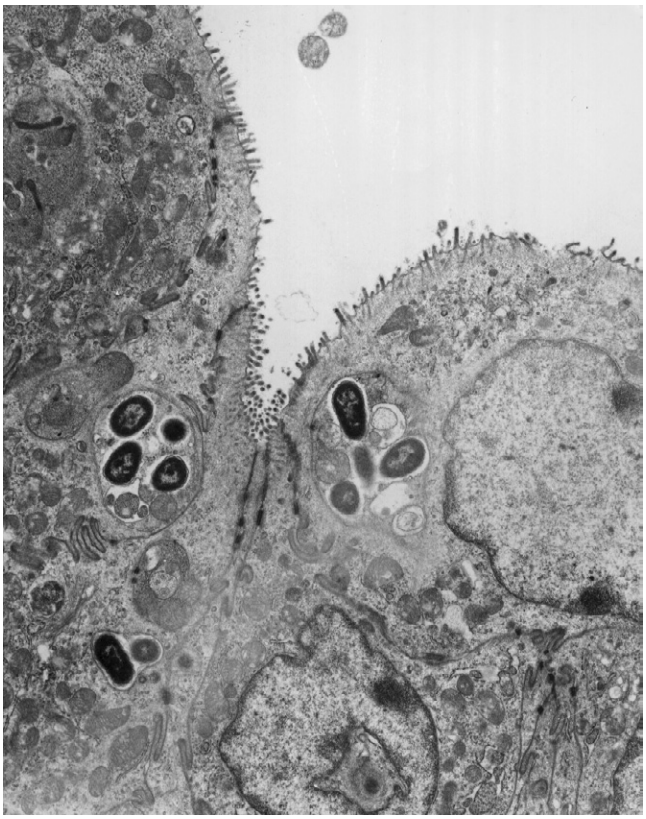

FIGURE 104-6 ■ Electron micrograph of enteroinvasive *Escherichia coli* infection of intestinal mucosa. The intracellular location of the bacteria clearly is seen within membrane-bound vesicles in two adjacent infected cells. The pathogenesis of enteroinvasive *E. coli* infection involves the invasion of intestinal cells and local cell-to-cell spread, as shown here, by a mechanism identical to that of *Shigella* spp. (Courtesy Saul Tzipori, D.V.M., Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)

The invasive process for EIEC is thought to be the same as that for *Shigella* spp. It involves four main steps: (1) initial entry into cells, (2) intracellular multiplication, (3) intracellular and intercellular spread, and (4) host-cell killing. The process is complex and involves multiple genes on the invasion plasmid and the chromosome.[1,10,253] Of interest, intracellular *Shigella* and likely EIEC are able to escape autophagy.[10] They additionally take advantage of the immune response to promote an invasive phenotype.[253] EIEC produces toxins reported to be structurally distinct from the Shiga toxin of *Shigella dysenteriae* type 1 and the Shiga toxins 1 and 2 of EHEC.[67] Nonetheless, studies suggest that EIEC toxins possess many properties in common with the Shiga family of toxins, including the ability to cause fluid secretion in animal models.[67] EIEC may contain a plasmid-borne gene that encodes a 63-kDa protein named *ShET2* (*Shigella* enterotoxin 2); a mutation in this gene substantially decreases the enterotoxic activity of the parent strain.[155] The virulence of EIEC is

notably less severe than that of *Shigella*. Several groups have noted that the expression of virulence genes by EIEC using in vitro models of infection is diminished in contrast to *Shigella*.[229,231] However, the differences leading to less severe disease in vivo are still not clear.

Enteroaggregative *Escherichia coli*

The pathogenesis of EAEC includes adherence to the intestinal epithelium as a thick biofilm, accompanied by mucus hypersecretion, intestinal damage, and induction of an inflammatory response. Most of these phenotypes seem to be mediated by a set of bacterial cytotoxins and enterotoxins.[89]

Adherence and colonization of the intestinal epithelium are mediated by pili called *aggregative adherence fimbriae*, of which several allelic variants exist. EAEC may colonize the large and small intestines.[93] All known aggregative adherence fimbriae variants are encoded on high-molecular-weight virulence plasmids collectively termed *pAA*. Also encoded on pAA is a transcriptional activator of the fimbrial genes, AggR. AggR is emerging as a global regulator of virulence functions in EAEC[57]; also under AggR control is a gene encoding a surface protein nicknamed *dispersin*. In the absence of dispersin, the aggregative adherence fimbriae adhesins collapse onto the surface of the bacterium, rendering it unable to colonize the intestine (J. Nataro, unpublished data, 2004). Several cryptic genes, including a large chromosomal locus, also are under AggR control.

Damage to the intestinal mucosa has been linked to the presence of a secreted enterotoxin named plasmid-encoded toxin (Pet).[63] Pet is a protease that is internalized by target epithelial cells, where it cleaves cytoskeletal proteins, including spectrin. The net effect of these cleavage events is induction of fluid, secretion of electrolytes, and, ultimately, exfoliation of cells from the mucosal surface.[92]

EAEC strains also harbor a homolog of the ETEC heat-stable toxin, enteroaggregative *E. coli* heat-stable enterotoxin[210] and a chromosomally encoded toxin termed *Shigella* enterotoxin 1.[68] Inflammation by EAEC has been linked to the expression of the bacterial flagellum, although studies in polarized epithelial monolayers suggest that additional factors under control of AggR also are required.[89]

Diffusely Adherent *Escherichia coli*

As their name implies, DAEC are categorized by their adherence pattern on Hep-2 cells. Their pathogenesis is not well delineated. They characteristically contain nonfimbrial adhesins referred to as Afa/Dr adhesins (Afa/Dr DAEC). Along with a fimbrial adhesin, F1845, found in prototypical strain C1845 and a majority of DAEC strains, these adhesins bind to human decay-accelerating factor and, depending on the subtype of DAEC, carcinoembryonic antigen–related molecules.[108,121,215] Binding then leads to invasion by a zipperlike mechanism[107] and a resulting inflammatory response.[15,20,21,35,215] Few virulence factors have been elucidated for DAEC. However, Sat, a member of the autotransporter family of toxins, has been found in DAEC strains thought to be diarrheagenic, causes lesions and triggers autophagy in vitro in epithelial cells, and causes intestinal damage in an animal model.[85,126,241]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diarrheogenic *E. coli* can be identified best by detecting their defining virulence genes. Although many molecular tests are described for this purpose, few laboratories in the United States use them. For most pathotypes, consultation with an expert, such as the senior author or the *E. coli* reference laboratories at the CDC, is recommended. Detection of *E. coli* generally is indicated for severe and persistent diarrhea lacking any other diagnosis (particularly in returning travelers) or in the setting of diarrheal outbreaks of unknown cause. With the exception of EHEC, most infections caused by diarrheogenic pathotypes are self-limiting.

Because of the potential of EHEC to cause serious sequelae, establishing a specific diagnosis is of clinical and epidemiologic importance. The earlier in the course of illness that a stool specimen is obtained, the more likely that *E. coli* O157:H7 will be recovered[244]; recovery more than 7 days after onset of diarrhea is unusual. The laboratory can use sorbitol-MacConkey agar to screen colonies for lack of sorbitol fermentation or substrates such as 4-methylumbelliferyl-β-D-glucuronide (MUG) for the production of β-glucuronidase; *E. coli* O157:H7 is almost uniquely sorbitol-negative and glucuronidase-negative. These techniques have limited sensitivity, with the sensitivity of sorbitol-MacConkey agar reported as 50 to 60 percent.[113] Some sorbitol-fermenting O157:H7 isolates and many other sorbitol-fermenting, non-O157 EHEC capable of causing severe illness and hemolytic-uremic syndrome would be missed by sorbitol-MacConkey agar.

Detecting Shiga toxin in stool specimens, either directly or after overnight broth enrichment, currently is the most sensitive nonmolecular method for identifying EHEC.[113] These tests are more sensitive than culture techniques and are not dependent on serotype. Commercial enzyme immunoassays for Shiga toxin have been approved by the U.S. Food and Drug Administration for either confirmation of isolates as toxin producers or rapid direct diagnosis based on the detection of Shiga toxin 1 or 2 in stool.[22,151] Despite the detection of Shiga toxin by these rapid assays, isolation of the organism, usually performed at reference laboratories, remains crucial for serotyping and other epidemiologic purposes. Serotype-specific commercial antigen immunoassays also are available.[151]

Diagnosis of ETEC traditionally would require identifying the heat-stable or heat-labile enterotoxin genes in an isolate or, after isolation and growth in vitro, by DNA probes or by detecting their products using enzyme-linked immunosorbent assay (ELISA). Multiplex PCR assays for detection of toxins and colonization factor antigens have been developed and are rapid, sensitive, and being used with increasing frequency.[51,193] PCR techniques are additionally available that allow virulence

factors to be detected directly from stool or environmental sources without the need for performing culture.[32,130] A retrospective diagnosis can be made by detecting an increase in antitoxin antibody, especially for heat-labile enterotoxin. ELISA for colonization factor antigens of ETEC also could be useful.

EPEC can be detected reliably by DNA probes for the 60-Md EPEC adherence factor plasmid or by adherence to cells in culture. The ability of *E. coli* to adhere to HEp-2 cells in culture in distinct morphologies led to the description of EPEC, EAEC, and DAEC as different pathotypes (see Fig. 104-3). After a 3-hour incubation of bacteria with cells, EPEC adheres to the cell in tight microcolonies, referred to as the *localized adherence* pattern. Although it remains sensitive and specific for EPEC, this method has been replaced by molecular detection methods to detect the locus of enterocyte effacement island (via the intimin-encoding gene *eae*) and the EPEC adherence factor plasmid (often via detection of the bundle-forming pilus–encoding genes).[55]

EAEC can be detected by the presence of the aggregative adherence pattern in the Hep-2 adherence assay (Fig. 104-7). DNA probes and PCR are available to detect the AggR regulon, and these tests are likely to provide more specific detection of EAEC pathogens.[44]

EIEC is detected best using molecular techniques that are specific for detection of pathogenesis-related genes. Several multiplex PCR assays that allow the user to screen for multiple *E. coli* pathotypes simultaneously have been described.[14,127,178] Additionally, it is possible to differentiate between *Shigella* spp. and EIEC using these techniques,[177] which can be introduced readily into any molecular biology laboratory and produce excellent results.

DAEC can be detected by a diffuse adherence pattern on Hep-2 cells.[166,215] A probe, commonly used in epidemiologic studies, which targets *daaC*, part of the F1845 operon, has recently been shown to cross react with some strains of EAEC.[215,226] PCR methods are available for detection from stool.[140,215]

This photomicrograph shows the characteristic "stacked-brick" appearance of the aggregative organisms over the surface of the intestinal epithelium in vivo in the same manner described for EAEC adherence to HEp-2 cells in tissue culture. (Courtesy Saul Tzipori, D.V.M., Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)

PROGNOSIS

EPEC, EAEC, and ETEC do not cause systemic infections or complications except those resulting from dehydration or the consequences of nutritional depletion. The prognosis is related directly to the availability and adequacy of fluid therapy. When this need is dealt with correctly in an otherwise healthy and well-nourished patient, the principal complication is the rare instance of monosaccharide intolerance. In infants or young children in developing countries with protein-energy malnutrition, however, chronic diarrhea and progressive worsening of nutritional status frequently are observed, sometimes resulting in mortality. When food is withheld from either well-nourished or poorly nourished children, hypoglycemia may occur and produce seizures, coma, or death. Rarely, loss of water in excess of salt causes hypertonic dehydration, with serum sodium concentrations greater than 160 mEq/L, a situation that may cause seizures, coma, and death.

As noted earlier, EAEC has been associated with persistent diarrhea lasting longer than 14 days in young infants and children. Persistent diarrhea leads to nutritional deterioration, may be difficult to control, and may culminate in death from sepsis or other infections. Inflammatory diarrhea caused by EIEC also results in nutritional deterioration, with significant protein losses occurring via the gut.

EHEC infections can be followed by hemolytic-uremic syndrome and neurologic and intestinal complications. Ten percent of patients may die early in the course of the systemic phase of hemolytic-uremic syndrome. Although the renal failure of hemolytic-uremic syndrome may be reversible with good management of fluid and electrolytes and the use of dialysis as needed, permanent damage to the kidneys is, contrary to earlier more optimistic assessments, likely to occur in 25 percent or more of patients over the course of 1 or 2 decades, and many of them require permanent dialysis or transplantation in the future.[75] Symptoms of chronic renal disease may appear more than 1 year after the initial presentation of hemolytic-uremic syndrome, suggesting that follow-up of these patients should be continued for at least 5 years, even for patients who appear to be recovered.[195]

TREATMENT

In all age groups, the principal treatment of the intestinal manifestations of *E. coli* enteric infection is replacement of fluids and electrolytes; with maintenance of fluid balance, the disease is self-limited to 1 week or less in most patients and lasts no more than 2 weeks in nearly all patients. The earlier that fluid replacement therapy is begun, the better the prognosis, particularly considering that clinical signs of dehydration do not develop until a 5 percent loss of body weight occurs and that sustained

loss of more than 10 percent of body weight is incompatible with survival.

When shock is present (usually with altered consciousness and an absent or thready pulse) or oral rehydration is unsuccessful because of persistent vomiting, patients must be rehydrated by intravenous infusion of an isotonic electrolyte solution, such as lactated Ringer solution or normal saline. Alternatively, several prerequisites must be ensured for oral therapy: (1) the patient must not be in shock, (2) the patient must be fully conscious, (3) the patient must be able to drink (vomiting, particularly common in children, is not an absolute contraindication because frequent small oral feedings usually are largely retained; when the metabolic abnormality begins to reverse toward normal, vomiting ceases), (4) bowel sounds must be present, and (5) renal function must be normal. Current recommendations for oral rehydration in the United States and Europe suggest the use of hypotonic fluid containing 60 to 75 mEq of sodium per liter (along with potassium and carbohydrates). In the developing world, where cholera is a common occurrence, the World Health Organization recommends that a solution containing 75 mEq of sodium be used for all cases of diarrhea. Monitoring for electrolyte imbalances may be required. Rice-based solutions for oral rehydration currently are favored in many diarrheal centers because of their reduced osmotic load.[115] Additionally, zinc supplementation may be of benefit in reducing the duration of acute diarrhea and preventing further episodes.[25,115,234]

A prospective cohort study comparing *E. coli* O157:H7 hemolytic-uremic syndrome patients who developed oligoanuric renal failure requiring dialysis with patients with nonoligoanuric renal failure found that the patients who required dialysis had received less intravascular volume expansion and sodium than the patients who did not require dialysis, suggesting that intravascular volume expansion with isotonic fluid was protective for oligoanuric renal failure when given early in the course of O157 infection.[7] The authors advocate hospitalizing all children with suspected EHEC infection for volume expansion with isotonic fluids and close monitoring.

Although rehydration therapy is the cornerstone of management, antibiotic therapy should be considered in some cases. In most *E. coli*–associated diarrheal illnesses, the disease is mild and of short duration and no specific antimicrobial therapy is required. Studies to address this issue have found antibiotics to be beneficial in some circumstances. In traveler's diarrhea secondary to ETEC, antibiotic therapy can shorten the duration of illness and decrease its severity.[12,62] Prophylactic antibiotic therapy probably carries more risk than benefit, however, and generally is not recommended unless a significant reason exists for the traveler to require prophylaxis. Because of increasing rates of resistance to trimethoprim-sulfamethoxazole (TMP-SMX) it is no longer recommended for treatment or prophylaxis.[58] For moderate to severe traveler's diarrhea (both ETEC and EAEC), rifaximin, ciprofloxacin, and azithromycin for 1 to 3 days have been shown to have some efficacy. Rifaximin is not absorbed from the gastrointestinal tract, which provides a more favorable side effect profile. However, if symptoms occur, such as high fever (39.4°C [102.9°F]) or grossly bloody stools, suggesting a more invasive pathogen, azithromycin is recommended instead (10 mg/kg/day for 3 days in children older than 6 months; children younger than 1 year should be watched closely by a physician).[51,58] Fluoroquinolones (ciprofloxacin) are considered to have a potential undesirable side effect profile in children, although 1 to 3 days, as recommended for traveler's diarrhea, would likely be safe. Of note, resistance to fluoroquinolones does continue to increase, which warrants continued monitoring and judicious use.[139] Children in developing countries with ETEC diarrhea also may benefit from receiving antibiotic therapy.[145,161]

EIEC infection theoretically would benefit even more from antibiotic therapy, given its pathogenic similarity to shigellosis and the known benefits of the early use of antibiotics. No controlled studies have validated this benefit for EIEC, however. In experimentally induced disease, DuPont and colleagues[59] reported that parenteral ampicillin produced a bacteriologic cure and rapid clinical response with defervescence and improvement of diarrhea in adults. They have also used ampicillin in the pediatric population for severe dysentery caused by EIEC.[230] TMP-SMX and ampicillin are the current drugs of choice, although resistance has been reported.[6]

Immunocompromised hosts, especially children with AIDS, may require prolonged antibiotic therapy for protracted or recrudescent diarrhea, even when it is caused by bacteria that normally produce only self-limited disease. Malnourished children and children with other serious underlying illness also fit this category. In these patients, systemic invasion may develop along with associated complications, including shock and renal failure. In addition, prolonged carrier states are common findings, with frequent relapses requiring long-term antibiotic therapy for suppression of relapse.

Epidemic EPEC infection, especially in newborns, seems to be affected favorably by antibiotic therapy.[156] The potential for this pathogen to cause prolonged disease and a history of high rates of mortality in neonates suggest the need for antibiotic trials in this age group. Based on limited data, either TMP-SMX or oral nonabsorbable antibiotics, such as gentamicin or colistin, usually are recommended, although antibiotic resistance is common and may alter the choice of antibiotics based on local susceptibility patterns.[16,255]

Antibiotic treatment of EHEC is not recommended. Antibiotics in clinical use do not improve the course or prevent sequelae, and they may exacerbate the illness by promoting production and release of Shiga toxin.[9,27,40] In vitro data suggest that subinhibitory concentrations of TMP-SMX and other antibiotics may increase expression of Shiga toxin.[16,110,134] The most rigorous prospective study to address this question found that the cohort who received antibiotics had a higher incidence of hemolytic-uremic syndrome (of 25 patients who received antibiotics, 9 developed hemolytic-uremic syndrome) than the cohort who did not (of 234 patients who did not receive antibiotics, 27 developed hemolytic-uremic syndrome; $p < .001$).[261,262] Other studies have found no association.[171,204]

Notably, no studies have used a randomized placebo-controlled design, so the association may reflect selection bias because both the use of antibiotics and systemic

complications are associated with more severe disease. A meta-analysis[204] did not show a higher risk for hemolytic-uremic syndrome associated with antibiotics; however, this meta-analysis has been criticized because it included a study in which all of the patients received antibiotics[99] and because comparisons were made among different antibiotics, which may not induce similar sequelae.

Eculizumab, a monoclonal C5 antibody that targets terminal complement complex formation, has been shown in a small case series (n = 3) to be effective in improving refractory severe hemolytic-uremic syndrome.[119] Further follow-up of hundreds of patients in Germany who had Shiga toxin–positive EAEC during a 2011 continental outbreak and received eculizumab is ongoing.[170]

Antimotility agents such as loperamide generally are not needed and should be used cautiously if prescribed, with great attention paid to dosage, especially in very young patients.[245] Dysentery is a contraindication to the use of antimotility agents, which may be a risk factor for the development of ileus and abdominal distention.[3] The prolonged use of antimotility agents is reported to be associated with more serious systemic complications of EHEC infection and is not recommended.[40,41]

In most instances of *E. coli* diarrhea, the clinician is left to make therapeutic decisions without knowing the etiologic agent responsible. For reasons already outlined, routine diagnostic microbiology laboratories cannot distinguish pathogenic from nonpathogenic *E. coli*, with the exception of classic EPEC serotypes and Shiga toxin–producing *E. coli*, including O157:H7 EHEC. Clinical decisions regarding the administration of antibiotic therapy are made on purely clinical grounds with criteria such as the history, duration, and severity of the illness; the age and immunologic competence of the patient; and the nature of the diarrheal stool (e.g., watery, inflammatory, bloody, or dysenteric). Empirical antimicrobial therapy is more justifiable for immunocompromised hosts, for patients with prolonged or severe illness or a history of relevant risk factors (e.g., specific food ingestion, travel, or exposure to known contacts), and for cases of inflammatory or dysenteric illness.

Research on alternative treatments of EHEC and prevention of hemolytic-uremic syndrome is ongoing. A synthetic verotoxin receptor, SYNSORB Pk, was not shown to prevent death, dialysis, or serious extrarenal events in a trial of 145 children with EHEC-induced HUS.[252] Although antibodies against *E. coli* O157 intimin were protective for colonization and disease in a pig model,[52] plasmapheresis and intravenous immunoglobulin have not been shown to ameliorate hemolytic-uremic syndrome in humans.[192,256] Investigation of monoclonal antibodies directed against Shiga toxin are under way.[252] The complete genome sequence of *E. coli* O157:H7 is now known and may lead to greater understanding of the pathogenesis of hemorrhagic colitis and hemolytic-uremic syndrome and perhaps innovative approaches to treatment and prevention.[90]

PREVENTION

Epidemic nursery outbreaks of diarrhea in newborns can be controlled by the application of classic principles of preventive medicine. Prompt diagnosis and treatment and scrupulous attention given to details of hand washing and environmental sanitation to eliminate person-to-person transmission are still effective, whereas prophylactic antimicrobials have no role. Outbreaks in neonatal nurseries can be contained by epidemiologic control measures such as cohorting; by screening staff for carriage; and, if necessary, by closing the unit until it is decontaminated. In contrast, preventing sporadic cases of *E. coli* diarrhea is difficult. In communities with obvious deficits in water supply and feces disposal, correction of these problems would lead to a diminished incidence of diarrheal diseases in general.

For traveler's diarrhea, avoidance of contaminated sources such as tap water, unpeeled fresh fruits, and large quantities of ice can be effective in prevention. Several studies additionally indicate that prophylactic antibiotics can protect adult travelers, at least for a limited time.[84] The risk for selection of resistant organisms and drug side effects limits the use of antibiotic prophylaxis to short-term travelers with business or diplomatic missions that would be hindered significantly by an episode of diarrhea. Fluoroquinolones, azithromycin, and rifaximin have been evaluated for prophylaxis and presumptive treatment, and all are efficacious.[222] Some evidence has been presented for the efficacy of bismuth compounds, such as bismuth subsalicylate, for the prevention of ETEC diarrhea in adults. The concern for bismuth toxicity with prolonged use in young children would render it a problematic solution for pediatric *E. coli* diarrhea and its prevention.

ETEC vaccine development has been propelled by the observation that ETEC infection confers some protection from reinfection with the same strain,[233] also evident in the decreasing rates of infection in children older than 5 years.[181] The challenge is that more than 25 colonization factor antigens have been identified, and strain serotypes vary tremendously across the world.[78] As noted previously, however, it also is known that certain serotypes and colonization factor antigens are most common (i.e., colonization factor antigens I, II, and IV) and tend to co-segregate.[74,78,260] This factor would limit the antigenic variability needed in an effective vaccine. Many isolates of ETEC expressing only heat-labile enterotoxin do not express known colonization factors and would be unaffected by a colonization factor antigen–based vaccine. Although no ETEC vaccine currently is licensed and available, several approaches have been attempted. Dukoral, a vaccine licensed in Europe and Canada for prevention of cholera, has been demonstrated to have some short-term efficacy against ETEC-associated traveler's diarrhea and may be useful for travelers to high-risk areas.[102] Among the most successful ETEC-specific vaccines to date is one composed of recombinant cholera toxin B (as a surrogate for the LTB toxin subunit) with strains of formalin-killed ETEC expressing the most prevalent colonization factor antigens in developing countries (rCTB-CF ETEC).[236] This vaccine was found to prevent 77 percent of nonmild ETEC diarrhea in travelers to developing countries.[181,202,236] In a study of Egyptian children, however, it was not efficacious in preventing disease.[29,181] Studies are now ongoing to increase the expression of colonization

factor antigens in a vaccine construct and improve the immune response to these antigens.[236]

Other avenues of vaccine development that have been pursued include live, attenuated ETEC vaccines[136] and subunit vaccines. Heat-stable enterotoxin does not create a significant immune response; however, heat-labile enterotoxin is a known adjuvant similar to cholera toxin and has been conjugated to heat-stabile enterotoxin.[29,78,128,266] Concerns for human use of this construct come, however, from the homology of heat-stabile enterotoxin to guanylin, which is produced endogenously.[29,50] Live, attenuated *Shigella* vaccine vectors also are being studied in an attempt to elicit a mucosal immune response. Researchers have studied new methods of delivering antigens to the mucosa, including encapsulation in microspheres, delivery in recombinant foods,[237,238,240] and a transcutaneous heat-labile enterotoxin patch vaccine.[72,135] Finally, new vaccine candidates are being identified, such as the EtpA adhesin that has been shown to elicit an immune response and offer some protection in mice.[198,199] Although no vaccine is yet licensed in the United States, work continues to advance in this field in an attempt to decrease the incidence and severity of morbidity from dysentery in the developing world and from traveler's diarrhea.

Vaccine development for other diarrheogenic *E. coli* strains lags behind that for ETEC. Because EHEC-induced hemolytic-uremic syndrome is a rare disease, vaccine development for humans is limited. However, one group is pursuing vaccination as part of the primary infant series because young age is a risk factor for the development of hemolytic-uremic syndrome. An O157:H7 O–specific polysaccharide conjugated to recombinant exotoxin A of *Pseudomonas aeruginosa* (O157-rEPA) vaccine was shown to be safe and immunogenic in children in a phase 2 study.[5,138] Vaccine development for cattle, the major reservoir, is ongoing[225] and has now yielded two available cattle vaccines.[138] A vaccine composed of type III secreted proteins resulted in decreased shedding of *E. coli* O157:H7 in contrast to controls, although prevalence of shedding increased over the study period. Repeat vaccination of cattle may serve as a mode to decrease human exposure to EHEC.[179]

CHAPTER 105

KLEBSIELLA

Randall G. Fisher

Klebsiella is a genus of Enterobacteriaceae, a frequent cause of nosocomial pediatric infection. Classically described by Friedländer[42] as a cause of pneumonia, *Klebsiella* can cause infections of the urinary tract, lung, and central venous catheters in high-risk newborns and immunocompromised older children.[20]

BACTERIOLOGY

Klebsiella organisms were named for Edwin Klebs, the noted German bacteriologist.[99] Distinguishing features of *Klebsiella* spp. include the absence of motility and the presence of a polysaccharide capsule that gives rise to

large mucoid colonies on solid media. The organisms are oxidase-negative and citrate-positive; they ferment inositol and hydrolyze urea but do not produce ornithine decarboxylase or hydrogen sulfide. Acetoin and 2,3-butanediol predominate over acidic end products during sugar fermentation (positive result on the Voges-Proskauer test). Four species of *Klebsiella* commonly are agreed on by microbiologists: *Klebsiella pneumoniae* (the most common human pathogen), *Klebsiella oxytoca* (a less common human pathogen), *Klebsiella terrigena*, and *Raoultella planticola*. Previously, *R. planticola* was recovered almost exclusively from soil and aquatic environments; reports now suggest that this organism may be a relatively common neonatal pathogen in some parts of the world.[106,130] *R. planticola* may express virulence factors similar to those of *K. pneumoniae*.[107] Organisms are defined serologically by their capsular polysaccharide (K antigens) and lipopolysaccharide (O antigens). Significant cross-reactivity exists between the capsule of some pneumococci (e.g., 19F) and *Klebsiella*.[79] The reader is referred to a review by Podschun and Ullman[105] for a detailed description of *Klebsiella* spp.

EPIDEMIOLOGY

Friedländer[42] proposed that *K. pneumoniae* was the most common cause of community-acquired pneumonia, an observation that was refuted by Fraenkel's[40] observations on pneumococcal pneumonia. *K. pneumoniae* accounts for fewer than 10 percent of hospitalized cases of pneumonia in adults.[22] *Klebsiella* spp. now are in greatest evidence as opportunistic nosocomial pathogens of the urinary tract, respiratory tract, biliary tract, and bloodstream. In one survey of the Centers for Disease Control and Prevention, the infection rate of nosocomial *K. pneumoniae* was 16.7 infections/10,000 patients discharged.[61] Hand carriage generally is regarded as the common mode of transmission.[46] Environmental sources of *Klebsiella* spp. include contaminated blood pressure monitoring equipment,[112] ventilator traps,[46] dialysate,[75] ultrasound coupling gel,[44] dextrose solution,[77] and hand disinfectant.[115] The emergence of plasmid-mediated, β-lactamase resistance can be responsible for the rapid spread of resistant organisms to susceptible patients in intensive care units (ICUs).[12,14] Outbreaks may be complex; patient-to-patient transmission of epidemic strains containing different plasmids may be interspersed with sporadic, nonepidemic *Klebsiella* infections.[14] *Klebsiella* spp. are second only to *Escherichia coli* as causes of sepsis,[45] with the highest rates of infection being reported from larger hospitals affiliated with medical schools.

Klebsiella spp. commonly are highlighted as pathogens of debilitated adults and alcoholics,[68] but by 1985, nearly 50 percent of reported outbreaks of *Klebsiella* were in neonatal ICUs.[61] Outbreaks in newborns continue to occur frequently worldwide.* Most outbreaks in newborns have been associated with *K. pneumoniae* infection, but scattered outbreaks of *K. oxytoca* infection in nurseries also have been reported.[8,129] A high percentage of infants in ICUs may become colonized with hospital strains of *Klebsiella*.[51] In one longitudinal study in which weekly rectal swabs were cultured, 80/368 (22%) neonates in an ICU harbored extended-spectrum β-lactamase (ESBL)–producing *Klebsiella* spp.[17] Infecting organisms have been isolated from care providers and from mothers of colonized infants.[26] One report described an outbreak among newborns associated with infestation of a neonatal unit by cockroaches colonized with infecting *Klebsiella* strains.[27] *Klebsiella* may spread from newborn units to adult units; interhospital and international spread of resistant strains has been described.[25,33,121] In a newer report, 31 neonates became colonized, 10 were infected, and 5 died from a neonatal ICU (NICU) outbreak in Maryland. Understaffing of an overcrowded NICU was thought to be important in the genesis of the outbreak.[128] In another NICU outbreak, the use of proton pump inhibitors and prior receipt of third-generation cephalosporins were identified as the principal risk factors for colonization and infection with an ESBL-producing strain.[49] Outbreak control usually depends on cohorting, careful hand washing, and intensive cleaning. However, *K. pneumoniae* isolates that are extremely antibiotic resistant also may be more resistant to chlorhexidine; cleaning with this agent in such cases may provide a selective advantage to the resistant strain.[95]

Ribotyping, pulsed-field gel electrophoresis, and DNA amplification techniques have proved valuable in characterizing *Klebsiella* strains associated with outbreaks.[81,123,124] Experimental techniques include multiplex real-time polymerase chain reaction, which can identify carbapenem-resistant *K. pneumoniae* strains in 2 hours.[127] The modified Hodge test is used in resource-limited settings and works quite well at identifying organisms that produce carbapenemases.[4] Different ribotypes that share plasmids conferring antibiotic resistance can be responsible for pediatric infections in a particular institution.[14] Strains expressing ESBL may become endemic and may present a complex and diverse pattern of production of enzymes with resistance to β-lactamase inhibitors.[34,39] Although broad-spectrum resistance to β-lactams and carbapenems[83] has been described, some longitudinal studies have shown that the frequency of ESBLs in *K. pneumoniae* isolates is decreasing.[118] Active surveillance, carrier cohorting, and increased barrier protection resulted in a decrease in the frequency of KPC-producing *K. pneumoniae* in one Greek hospital.[109]

PATHOPHYSIOLOGY

Pneumonias caused by *Klebsiella* most commonly arise from colonization of the upper respiratory tract, followed by aspiration of organisms to the lower respiratory tract. Some degree of gram-negative oropharyngeal colonization is a normal finding in newborns. The oropharynx of nearly one third of healthy newborns is colonized by gram-negative rods, including *Klebsiella*, by the time infants reach 1 month of age; colonization rates generally are lower in breast-fed infants.[11] Antibiotic pressure in high-risk newborns and older children has been observed to promote overgrowth of *Klebsiella*.[13,120] Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults; oral

*References 2, 9, 26, 33, 54, 103, 114.

colonization with gram-negative rods is increased during illness,[64] after postoperative viral infections,[65,111] and in debilitated adults.[84] Increased adherence of gram-negative rods to oropharyngeal cells contributes to increased colonization.[65] Elastase made by polymorphonuclear cells contributes to such colonization by reducing the fibronectin coating of sugar receptors.[30] The capsule plays an initial role in interactions of epithelial cells but is not required for an adhesin interaction with the cell surface.[37] Adherence properties may be affected by plasmid content[32] and may be transferred between *E. coli* and *K. pneumoniae*.[60]

In animal models of sepsis, capsular polysaccharide (K antigens) is a virulence factor; monoclonal antibodies to the K antigens reduce the severity of illness in mice.[78] In a mouse model of urinary tract infection, the K antigens seemed to be more important in infection than the lipopolysaccharide (O antigens), and clinical strains deficient in lipopolysaccharide retained virulence by resistance of capsule to complement.[3,21] In one series of adult patients, capsular type K2 frequently was associated with asymptomatic bacteriuria and cystitis, but not pyelonephritis; the presence of type 1 fimbriae bore a closer relationship to upper urinary tract infection.[108] In a retrospective study, patients bacteremic with hyperviscous strains were more likely to develop invasive localized disease, such as liver abscess, meningitis, pleural empyema, or endophthalmitis.[80] Patients bacteremic with the hypermucoviscous phenotype are more likely to come to the hospital from the community and less likely to have underlying disease states, suggesting increased virulence.[69] Liver abscess is almost always caused by hypermucoviscous organisms[38]; surprisingly, disruption of the genes that produce this phenotype did not affect serum sensitivity in vitro and did not alter abscess formation in a mouse model.[74] In another study, the lipopolysaccharide O1 was found to be important; O1 serotypes had higher serum resistance and mutation of the O1 gene greatly reduced the virulence of the organism in a mouse model.[58] Neutrophils play an important role in clearance of *Klebsiella*, and phagocytosis is augmented by leukotrienes.[85]

CLINICAL MANIFESTATIONS

Klebsiella infection shows little clinical distinction from diseases produced by other enteric pathogens. The organism generally is less common than group B streptococcus or *E. coli* as a cause of early-onset or late-onset infection in newborns.[47,88] Investigators from Spain,[54] however, reported one 7-year interval in which *K. pneumoniae* was the most common cause of bacteremia in newborns. In Yemen, gram-negative rods accounted for almost all of 90 cases of neonatal sepsis; *E. coli* outnumbered *K. pneumoniae* by only one case.[2a] Risk factors for neonatal *Klebsiella* infection include prematurity, presence of indwelling catheters, previous antibiotic treatment, and parenteral nutrition.[114] Infection in newborns is characterized by typical features of pneumonia, sepsis, and meningitis.[88] In one unusual case, *K. pneumoniae* bacteremia manifested on day 4 of life as a morbilliform maculopapular exanthem, more severe on the face. The infant was afebrile, but the mother had had fever in the peripartum period, and the amniotic fluid had been meconium-stained.[23]

Although hepatic abscesses have been associated principally with adults with poorly controlled diabetes mellitus, one case report described a 32-week-gestation neonate with *K. pneumoniae* sepsis who developed a liver abscess large enough to be noted on physical examination as an abdominal "lump."[125] In adults, hepatic abscess occasionally is complicated by endophthalmitis or central nervous system infection, with devastating outcomes. A study from Taiwan found that infection with genotype K1 was the only significant risk factor for these complications.[36] This series also revealed that 8/19 (42%) of the complicated K1 strain infections occurred in patients without identifiable underlying medical disease.[36] Other investigators have emphasized that serotype K2 also can be virulent in patients with liver abscess.[43] Careful study of the pathophysiology and epidemiology of complicated *K. pneumoniae* liver abscesses is ongoing, and the picture is likely to continue to be clarified.

Klebsiella spp. have been isolated commonly from blood and peritoneal fluid in outbreaks of necrotizing enterocolitis.[48,92] Less common manifestations in infants include toxic epidermal necrolysis,[52,102] conjunctivitis,[76] parotitis,[24] retropharyngeal abscess,[28] subdural hematoma,[97] psoas abscess,[5] and renal abscess.[126]

Klebsiella is an unusual cause of infection in an otherwise healthy older child. The classic Friedländer pneumonia that occurs in debilitated adults[42] is rare in children. The identification of pulmonary infection should suggest the possibility of underlying immunodeficiency or significant malnutrition, if not suspected previously.[59,66] If pneumonia caused by *Klebsiella* does occur, progression to lung abscesses should be anticipated.

Lung abscesses may develop within days to weeks after *Klebsiella* infection. Formation of abscesses occurs more frequently during *Klebsiella* pulmonary infection than during any other community-acquired infection.[22] A rare but devastating outcome is massive pulmonary gangrene—the rapid total destruction of part of the lung presumed to be due to vascular compromise. This complication is heralded by radiographs that show small cavities that later coalesce into a large cavity with an intracavitary mass of necrotic lung.[94,98] Some researchers speculate that *Klebsiella* lung infection is accompanied by coincident anaerobic infection that contributes to or is primarily responsible for the pathologic process.[22]

Catheterization of the urinary tract can be associated with urinary tract *Klebsiella* infection, but bacteremia is an uncommon complication in an immunocompetent child.[31,82] Approximately 10 percent of nosocomial urinary tract infections observed in infants after surgery are caused by *Klebsiella*.[31] Focal renal infection progressing to renal abscess has been described.[73] *K. pneumoniae* bacteremia has been associated with lesions of the gastrointestinal tract, presence of an indwelling central venous catheter, and neutropenia. Patients with short-bowel syndrome seem to be at greater risk than are patients with inflammatory bowel disease or malignancy for development of catheter-associated *Klebsiella* or *Enterobacter* bacteremia. *K. pneumoniae* was a constituent of polymicrobial bacteremia in 15 such patients (26%).[16] Mortality rates have ranged from 5 to 20 percent, with

higher death rates occurring in children infected with an aminoglycoside-resistant strain.[15,61] Pneumonia, shock, and disseminated intravascular coagulation are poor prognostic factors in children with underlying malignancy. Rare clinical presentations include multifocal osteomyelitis[72] and endophthalmitis.[86] Pediatric recipients of solid organ transplants may have high rates of acquisition of drug-resistant *Klebsiella*.[113] *Klebsiella* spp. have been described as a frequent pathogen in children and adults with sickle cell disease in West Africa.[1]

Of four patients who received organ transplants from people who had been infected with KPC-producing *K. pneumoniae*, one developed invasive infection despite tigecycline prophylaxis.[7] *K. pneumoniae* was the most common cause of bloodstream infection in children undergoing liver transplantation in Korea, accounting for 22 percent of all infections.[116] In New York City, *K. pneumoniae* was the second most common etiology of infection among adult liver transplant recipients. The mortality rate was 71 percent among those who contracted KPC-positive strains; the odds ratio for death was 4.9 for those with the KPC-producing isolates.[70]

Of six patients with clinical and colonoscopic findings suggestive of antibiotic-associated hemorrhagic colitis (pseudomembranous enterocolitis) but negative evaluation for *Clostridium difficile*, five had stool cultures positive for *K. oxytoca*.[57] All five patients had been receiving penicillin therapy. *K. oxytoca* was cultured from only 1.6 percent of 385 healthy controls. Additionally, the disease could be reproduced in a rat model when rats were inoculated with *K. oxytoca* and administered amoxicillin-clavulanate, but disease was not seen if rats were not given the injection and the antibiotic treatment.[57]

DIAGNOSIS

Klebsiella spp. characteristically grow as large mucoid colonies on MacConkey agar. Citrate-containing media can be used to facilitate isolation of *Klebsiella* strains because these organisms can use citrate as a sole carbon source.[99] Serotyping with specific antisera usually is determined by countercurrent immunoelectrophoresis or a Quellung test.[10] In situ hybridization techniques have been used to identify *Klebsiella* in phagocytes from blood specimens,[87] and restriction-enzyme analysis and ribotyping of clinical isolates have been used to characterize nosocomial spread of antibiotic-resistant strains.[14,50] Conventional, commonly used microbiologic methods may misidentify some *Klebsiella* spp., particularly *R. planticola* and *K. terrigena*.[93] Rarely, blood cultures have required longer than 72 hours of incubation for radiometric detection of *Klebsiella*.[89]

TREATMENT

Empirical antimicrobial therapy should be guided by an understanding of antimicrobial susceptibilities of *Klebsiella* in the hospital. Therapy with a cephalosporin plus an aminoglycoside (rather than a cephalosporin alone) has been associated with a more favorable outcome in patients with cancer who are infected with susceptible strains.[15] Antimicrobial therapy of *Klebsiella* spp. is made problematic, however, by the resistance to penicillins and cephalosporins conferred by ESBLs.[12,14,18,53] *Klebsiella* with ESBL are widely distributed, and regional differences in susceptibility occur.[67] Outer membrane protein changes and porin deficiencies of some strains can augment resistance to third-generation cephalosporins.[6,117] Some investigators have reported significant correlation between production of ESBL and resistance to ciprofloxacin.[101,122] Plasmid-mediated resistance to aminoglycosides also is common.[8,26,45,96] Endocarditis isolates that developed resistance to piperacillin-tazobactam and to ciprofloxacin during therapy have been reported.[131]

Effective treatment of multidrug-resistant isolates sometimes requires creativity or use of antibiotics no longer commonly employed. In one case report, a 15-year-old girl developed bacteremia with a meropenem-intermediate strain; bacteremia persisted despite thrice-daily administration of meropenem combined with gentamicin, to which the isolate was sensitive. Clearance was achieved eventually with meropenem administered as a continuous infusion.[35] In another case, bacteremia and peritonitis developed in a patient on continuous ambulatory peritoneal dialysis; infection persisted despite removal of the catheter and treatment with meropenem and amikacin (to which the isolate was intermediately resistant). Cure required a switch to intravenous polymyxin B.[100] Treatment of carbapenem-resistant strains is even more difficult. In vitro, the combination of doripenem and colistin produced bactericidal activity in 75 percent and synergy against 50 percent of colistin-resistant KPC-positive strains.[62] In an animal model, isolates that were carbapenem-resistant because of OXA-48 were more sensitive to ceftazidime than to piperacillin-tazobactam, imipenem, ertapenem, or cefotaxime.[91] New approaches to the treatment of so-called pan-resistant strains include the novel β-lactamase inhibitor MK-7655[56] and an antibacterial "designer peptide" called Api88, which binds a chaperone protein and rescues mice from lethal challenge.[29]

Antibiotic pressure is important in increasing the risk for development of resistant isolates.[110] In some nursery outbreaks, switching from gentamicin to amikacin has been associated with return of the susceptibility of *Klebsiella* isolates to gentamicin.[8,55] Imipenem or the combination of piperacillin and tazobactam may show good antimicrobial activity against multiply-resistant organisms.[63,104,110] The combination of β-lactamase and porin deficiency has been associated with resistance to imipenem,[19] and hyperproduction of some β-lactamases can limit the effectiveness of β-lactam–β-lactamase inhibitor combinations.[41] Experience with use of ciprofloxacin in young children is limited because of observations of irreversible cartilage injury in laboratory animals after administration of this quinolone. Successful treatment of a multidrug-resistant *K. pneumoniae* has been reported in a preterm infant, however, without observable short-term adverse effects.[71] Strict adherence to infection control policies that promote restricted antibiotic use, cohorting, and hand washing may help to prevent the spread of resistant *Klebsiella* strains.[8,26,51,90,119]

CHAPTER 106

Morganella morganii

Randall G. Fisher

Similar to *Proteus* and *Providencia* spp., *Morganella morganii* has emerged as an important nosocomial pathogen, most often associated with urinary tract or wound infections. Although most descriptions of infection are in adults, infections in children do occur.

BACTERIOLOGY

M. morganii (formerly *Proteus morganii*) is a motile gram-negative bacillus commonly found in the feces of humans, other mammals, and reptiles.[33] The organism was elevated to genus rank because of genetic differences from *Proteus*, with which it is otherwise biologically similar.[7] Most strains do not ferment lactose. *M. morganii*, *Proteus* spp., and *Providencia* spp. are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Similar to *Proteus* and *Providencia* spp., *M. morganii* produces urease, but this enzyme is unrelated genetically and serologically to urease produced by the other two genera.[21,33] In contrast to *Proteus* spp., neither *Providencia* spp. nor *M. morganii* shows swarming activity

on 1.5 percent agar[33]; *M. morganii* is ornithine positive, whereas *Providencia* spp. are ornithine negative. *M. morganii* organisms do not hydrolyze gelatin and do not produce hydrogen sulfide. For a detailed discussion of taxonomy and characterization of *M. morganii*, the reader is referred to the review by O'Hara and colleagues.[31]

EPIDEMIOLOGY

Similar to *Proteus* and *Providencia* spp., *M. morganii* organisms commonly are found in soil, sewage, and manure. Similar to *Proteus mirabilis*, *M. morganii* often invades the instrument-fitted urinary tract and surgical wounds; adults in inpatient surgical units have the greatest risk for colonization and infection.[1] Institutionalized elderly patients also are infected frequently with these organisms. Urinary tract colonization with *M. morganii* accompanying groin skin colonization in elderly individuals may account for the greater frequency of urinary tract infections in this population.[17] *M. morganii* accounted for nearly 10 percent of 145 consecutive complicated, multidrug-resistant urinary tract infections.[13] *Escherichia coli* and *P. mirabilis* account for most urinary tract infections in children, but *M. morganii* has been implicated in some cases of cystitis and pyelonephritis. In contrast to well-described nursery epidemics of *P. mirabilis* infection,[3,9] no *M. morganii* neonatal outbreaks have been described, and infections of the central nervous system are rare in newborns.[15,43] A fatal case of early-onset sepsis in which both the mother's lochia and the neonate's blood were culture positive has been reported. The baby died at 17 days of age despite appropriate antimicrobial therapy.[32] Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analyzing outbreaks.[35]

PATHOPHYSIOLOGY

Factors that predispose the urinary tract to invasion by *P. mirabilis* and *Providencia* spp. also may favor *M. morganii* colonization and infection. These organisms all split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.[6,29] The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH compared with *M. morganii* may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.[40]

CLINICAL MANIFESTATIONS

Urinary tract infection with *M. morganii* often is associated with an elevated urinary pH. Urolithiasis can occur, although perhaps less frequently than during *P. mirabilis* infection.[4] *M. morganii* has been recovered from less than 10 percent of adult bacteremic episodes, but mortality rates have exceeded 20 percent.[1] Approximately three fourths of all cases of adult *M. morganii* bacteremia are hospital associated.[24] In a series of 132 patients with bacteremia from Proteeae, preexisting biliary or hepatic disease (especially the presence of biliary drainage catheters) was associated with *Morganella* bacteremia.[24] In a series of 73 patients with *Morganella* bacteremia in Taiwan, 92 percent had at least one underlying disease, the most common of which was solid tumor. The only independent risk factor for mortality was inappropriate antibiotic treatment.[26] Other reported complications identified in immunocompromised or instrument-fitted patients include meningitis,[19,27] arthritis,[23,39] empyema,[20] peritonitis,[20] otitis media,[18] and skin infection.[2] Many cases of postoperative *M. morganii* endophthalmitis and panophthalmitis have been reported, as have rare cases of endogenous endophthalmitis, all in adults.[10,42,44,45] *M. morganii* has been recovered alone or in combination with other organisms from surgical wounds[13] and soft tissue abscesses in children.[8] A 12-year-old with meningoencephalitis, whose immune system was apparently normal, has been reported.[30] Another rare manifestation of *M. morganii* infection was pericarditis, seen in a child with X-linked agammaglobulinemia.[11] A 3-year-old boy developed hemorrhagic bullae and necrotizing fasciitis after being scratched by a chicken; cultures grew both *M. morganii* and enterococci.[25] Perinatal bacterial sepsis and brain abscess have been described.[36-38,43] In three more recently reported cases of early-onset neonatal sepsis, premature rupture of membranes and maternal receipt of antepartum amoxicillin were documented.[5,16]

DIAGNOSIS

M. morganii produces a reddish brown pigment when cultured on nutrient media supplemented with 5 percent tryptophan.[33] Production of urease and deamination of tryptophan help to distinguish this bacterium from other organisms. In contrast to the closely related *Proteus* and *Providencia* spp., *M. morganii* generally ferments only glucose and mannose and does not produce a red color on lysine iron agar.[33] *M. morganii* may be missed or mistaken for other organisms in the common circumstance of polymicrobial infection in a catheterized patient. In one series, *M. morganii* was among the most common bacteriuric species in patients on long-term catheterization but commonly was missed by reference laboratories.[14] The clinical laboratory should be directed to look for this organism, particularly in circumstances of nosocomial urinary tract infection and sepsis.

TREATMENT

Effective treatment of local infections or septicemia relies on appropriate choice of an antibiotic, often including an aminoglycoside, combined with surgical débridement and drainage of abscesses, as necessary. Antimicrobial susceptibility can vary widely among *M. morganii* and the related *Proteus* and *Providencia* strains, emphasizing the importance of species identification and susceptibility testing.[22,34] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[28] Most isolates are intrinsically resistant to

ampicillin and first- and second-generation cephalosporins. Some carry a chromosomal broad-spectrum AmpC β-lactamase that can be stably derepressed on treatment with third-generation cephalosporins, similar to *Enterobacter* spp., although it appears that this problem arises much less frequently among *Morganella* isolates.[12] Most urinary tract infections respond to treatment with third-generation cephalosporins. Failure to clear bacteriuria should alert the physician to the possibility of urolithiasis or structural abnormality[4]; stone removal or surgical correction of anatomic defects often is required for cure. The approach to the treatment of sepsis or serious infection of sites other than the urinary tract should be considered carefully in light of local susceptibility patterns, keeping in mind that isolates with AmpC β-lactamases may seem to be sensitive to cephalosporins on initial testing but develop resistance during therapy. Treatment failure, with prolonged culture-positive ventriculitis, has been described in an infant with *M. morganii* meningitis after initial therapy that included cefotaxime led to stable derepression of an AmpC β-lactamase, showing the potentially devastating clinical relevance of this phenomenon.[41] Aztreonam has shown effectiveness in therapy for 98 percent of multidrug-resistant strains.[13]

CHAPTER 107

Proteus

Randall G. Fisher

Proteus spp. are pathogens that are associated increasingly with pediatric illness. Neonatal meningitis and pediatric urinary tract infections are the most common childhood conditions in which these organisms are isolated, but infections of other organ systems have been described.

BACTERIOLOGY

Proteus spp. are motile, gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Rapid and abundant production of urease further differentiates *Proteus* spp. from *Providencia* spp.[37] *Proteus vulgaris* and *Proteus mirabilis* tend to form a thin, spreading growth (swarm) on the surface of moist agar media, often overgrowing other bacterial isolates. They also produce hydrogen sulfide and liquefy gelatin. *P. mirabilis* is distinguished from other *Proteus* spp. (e.g., *P. vulgaris*) by its inability to produce indole from tryptophan. Most indole-negative clinical *Proteus* isolates are classified by laboratories as *P. mirabilis;* however, in one study, 8 of 61 were found to be *P. penneri* when extensive biochemical testing was performed.[35] Disparate DNA content and anomalous biochemical and serologic reactions have caused *Proteus morganii* to be renamed *Morganella morganii* (see Chapter 106),[37] and both terms for this organism appear in the clinical literature. For detailed discussion of taxonomy and characterization of *Proteus* spp., the reader is referred to the review by O'Hara and colleagues.[49]

EPIDEMIOLOGY

Proteus spp. commonly are found in soil, sewage, and manure. Although they are normal inhabitants of the colon and perineum, their numbers can be increased in individuals receiving antibiotic therapy.[33]

First reported by Buisine and Henninot in 1949,[12] neonatal meningitis caused by *P. mirabilis* accounts for approximately 4 percent of all neonatal meningitis cases.[45] Outbreaks in nurseries have been attributed to contaminated equipment and human carriers. Vertical transmission from mother to infant has been confirmed by DNA fingerprinting and ribotyping methods.[9] In Becker's series[6] of *P. mirabilis* neonatal meningitis, all affected infants came from the same nursery and all were exposed to mist from an apparatus that yielded *P. mirabilis*. The importance of hand carriage was well documented by Burke and associates[13]; neonatal umbilical colonization and invasive disease were linked to a single nurse from whom *P. mirabilis* was cultured from her hands, rectum, and vagina. Ribotyping is a sensitive method for molecular characterization of isolates and may aid in analyzing outbreaks.[53]

Proteus infection after the first few months of life most commonly involves the urinary tract. Although *Escherichia coli* accounts for most urinary tract infections in children, *Proteus* spp. commonly are implicated in reported series of cystitis and pyelonephritis[8,23,34,50,70]; in a large pediatric series, they were the third most common cause of urinary tract infection, after *E. coli* and *Klebsiella pneumoniae*.[10] *P. mirabilis* is the most common species of *Proteus* isolated: it has been cultured more frequently from the urethra of uncircumcised than of circumcised male infants and has replaced *E. coli* as the most prevalent pathogen in one consecutive series of male patients presenting with initial urinary tract infection.[34,71]

Urinary tract infection with *Proteus* spp. is one of the most common presenting signs of urolithiasis in children,[19] and *P. mirabilis* supplants *E. coli* as the major urinary tract pathogen in children prone to renal stone formation.[8] Diagnosis of greater than 50 percent of pediatric urolithiasis cases is based on preceding urinary tract infection, and *Proteus* is responsible for 65 percent of these infections.[8] Isolation of this organism as a pathogen on urine culture should alert the physician to the possible presence of a urinary tract stone.

PATHOPHYSIOLOGY

Most cases of central nervous system infection caused by *Proteus* spp. occur in neonates and are thought to arise by bacteremic spread of the organism to the brain or meninges. Contiguous spread to the brain from localized infections is reported occasionally.[44,61] As is the case with *Citrobacter* meningitis, a propensity for formation of abscesses of the central nervous system remains unexplained. Rabbit models of *P. mirabilis* meningitis have shown that in vivo concentrations of gentamicin necessary to produce bacterial killing are 10 to 30 times higher than the concentrations predicted from in vitro susceptibility testing.[68] Reduced aminoglycoside effect may be secondary to depressed cerebrospinal fluid pH associated with *P. mirabilis* infection.[68] Whatever the mechanism, lack of effective antimicrobial activity in the ventricles accounts partly for the persistence of organisms at these sites.

Crystallization of urinary catheters and stents leads to obstruction of outflow of urine. Urease produced by *Proteus* infection causes calcium phosphate and magnesium phosphate to precipitate and accumulate in the catheter lumen.[67] This process is less likely to occur when the urine is dilute and acidic.[67] Mannose-resistant/*Proteus*-like fimbriae (often shortened to MR/P fimbriae) are important in the formation of biofilms on catheter material.[57] *Proteus* isolates obtained from catheter-associated urinary tract infection have increased swarming motility and form biofilms more readily than *Proteus* isolates from stool of healthy volunteers.[28] Methods of preventing crystallization, including the use of low-energy acoustic waves generated by electrically activated piezo elements, which interferes with docking and attachment, are being studied.[27] More conventional approaches include coating the catheters with agarose[66] and impregnating catheters with chlorhexidine and triclosan.[22]

Numerous factors may predispose the urinary tract to invasion by *Proteus* spp. *Proteus* spp. split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.[11,47] The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH when compared with *M. morganii* may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.[60] Biochemically complex struvite ($MgNH_4PO_4$) stones provide a refuge for *Proteus* organisms and form a barrier to effective antimicrobial therapy.[8] Formation of struvite stones is a major cause of urinary bacterial persistence in women without azotemia,[65] and a similar case probably can be made for pediatric patients with urolithiasis. *P. mirabilis* ureases showed lower affinities for substrate but hydrolyzed urea 6 to 25 times faster than enzymes from other species, which may explain the frequent association of this species with formation of stones.[30]

Organisms have been shown to be taken up by human renal epithelium, by an actin-independent mechanism.[15] Pili may enhance the virulence of *Proteus* in pyelonephritis by increasing adherence of organisms to the renal pelvis.[57,62] Flagella have been implicated in the spread of this organism in the urinary tract[40]; the ability to invade host uroepithelial cells is coupled closely with the ability of *P. mirabilis* to differentiate into hyperflagellated, filamentous swarm cells capable of rapid spread on the surface of moist agar media.[3] The role of fimbriae as a factor predisposing to ascending infection is less clear.[5,43] Swarming behavior might inherently assist ascending colonization of the urinary tract, as shown in a mouse model of infection.[4] A putative gene regulator for swarming behavior (RsbA) may act to identify environmental conditions that favor swarming.[7] The reader is referred to the review by Rozalski and colleagues[58] for a more in-depth review of *Proteus* virulence factors.

A growing body of literature suggests that adult rheumatoid arthritis may be triggered by infection of the urinary tract with *Proteus* spp. In one study, increased levels of total and class-specific IgG antibodies directed at three *Proteus* peptides were found in patients with rheumatoid arthritis but not in control subjects.[56] Patients with active disease had measurable IgM, and a positive correlation was found between antibody indices and inflammatory markers.[56] This association is still speculative and is being investigated; at this time, no suggestion has been made that juvenile rheumatoid arthritis is related in any way to *Proteus* infection.

CLINICAL MANIFESTATIONS

P. mirabilis can produce a broad spectrum of symptoms associated with neonatal infection. Most patients have typical symptoms of early-onset neonatal sepsis, including nonspecific lethargy, fever, and poor feeding; manifestations of sepsis may include septic arthritis and osteomyelitis. In a few patients the disease presents after the first week of life. Meningitis may occur with either early-onset or late-onset disease. Brain abscesses associated with subtle clinical abnormalities rarely develop for weeks to months before presentation.[13] *Proteus* brain abscesses are associated with a high degree of mortality, frequent complications, and increased risks of neurologic deficits in survivors.[17,31,39,63] Hydrocephalus is a particularly frequent complication and should be anticipated. Destruction of the brain may progress to porencephaly or compartmentalization of ventricles and often requires surgical intervention.[31] Computed tomography is useful, especially in diagnosing and following progression of cerebral complications.[63]

Urinary tract infection with these bacteria involves predominantly younger patients and often is associated with elevated urinary pH; clinical findings and urine abnormalities often are less striking than in patients with *E. coli* urinary tract infections.[34] Thirty percent of patients may show recurrent infection during the 12 months after receiving initial treatment.[34] Indwelling urinary catheters increase the risk for *Proteus* colonization and infection. Long-term indwelling urinary catheters or stents may become blocked by encrustations of aggregated struvite crystals; prolonged colonization with urease-producing *P. mirabilis* is associated with this complication.[38] *P. mirabilis* is the most common pathogen associated with xanthogranulomatous pyelonephritis,[2] which can mimic Wilms tumor and usually is not seen in childhood except in malnourished patients.

Proteus spp. often are implicated as agents of septicemia in adult patients and account for approximately 8 percent of gram-negative bacteremias in this group.[20,36] In 60 percent of *Proteus* bacteremic episodes in adults, the urinary tract has been determined to be the source[20]; no anatomic source is identified in 20 percent of cases of *Proteus* bacteremia. *P. mirabilis* and *P. vulgaris* are the species responsible for most cases of *Proteus* bacteremia. The overall incidence of gram-negative enteric bacteremia in pediatric patients is lower than that of adults; 5 percent of such cases are caused by *Proteus* spp.[20] As in adults, the genitourinary tract is the source identified most frequently.[20] Predictors of bacteremia in adults with *Proteus* urinary tract infection are community acquisition, hydronephrosis, bandemia greater than 10 percent, a C-reactive protein value greater than 10 mg/dL, and hypothermia or hyperthermia at diagnosis.[14] Mortality rates average less than 40 percent and strongly depend on the severity of underlying disease in the host.[20,36]

Osteomyelitis,[32,52,68] pneumonia,[20,36,54] mastoiditis,[44] and wound infections[36] also occur. Rarely, native-valve endocarditis has been caused by *P. mirabilis*.[16] Severe multifocal osteomyelitis requiring bilateral above-knee amputation for cure has been reported in a patient with human immunodeficiency virus infection despite a reasonably good $CD4^+$ cell count.[51] *Proteus* spp. have been isolated commonly from chronic suppurative otitis media on several different continents.[24,69] Reports that *Proteus* spp. are major pathogens of otogenic brain abscess in pediatric and adult patients support this association.[25,55] Pediatric osteomyelitis secondary to contiguous infection of traumatized soft tissue often is polymicrobial, and *Proteus* spp. have been implicated as co-pathogens in at least 10 percent of such cases.[52] Sickle cell anemia is a risk factor.[1,32]

DIAGNOSIS

Proteus is suspected readily because of its ability to swarm on the surface of moist agar. A selective medium developed for the isolation of *Proteus* organisms relies on the ability of all members to produce a dark brown pigment in medium containing DL-tryptophan.[26] Production of urease, lack of indole production from tryptophan, and a positive result with ornithine decarboxylase testing distinguish *P. mirabilis* from *Providencia* spp. and other *Proteus* spp.[37]

TREATMENT

Treatment of meningitis caused by *Proteus* spp. should conform to standard regimens recommended for gram-negative meningitis. *P. mirabilis* usually is sensitive to ampicillin, however, and this drug alone or combined with an aminoglycoside often is suitable therapy when the identity and susceptibilities of the infecting organism are known.[59] A third-generation cephalosporin often is an alternative, but resistant extended-spectrum β-lactamase–producing strains and β-lactamase inhibitor–resistant strains have been described in pediatric patients.[18,40] Consecutive lumbar punctures should be performed for *Proteus* meningitis until cerebrospinal fluid cultures are sterile. A minimum of 2 weeks of antibiotic therapy is recommended after bacteriologic cure has been achieved. Ventricular aspiration or drainage of abscesses may be required to direct therapy, based on persistence of organisms at these sites. Open drainage of abscesses often is necessary, but resolution of abscess formation with the use of antibiotic therapy alone has been reported.[64] Intraventricular antibiotics are not of proven benefit in terms of mortality or morbidity but

have been used to clear ventricular colonization. A 15-year-old boy with *Proteus* mastoiditis and meningitis has been treated successfully with intravenous trimethoprim-sulfamethoxazole.[44]

Effective treatment of local infections or septicemia relies on appropriate choice of antibiotics, often including an aminoglycoside, combined with surgical débridement and drainage of abscesses as necessary. Many experts recommended "double coverage"—a cell wall–active agent plus an aminoglycoside—especially when the infection is severe or is caused by an indole-positive strain. In a large, three-continent longitudinal survey, approximately 5 percent of *P. mirabilis* strains exhibited phenotypic extended-spectrum, β-lactamase resistance patterns.[21] In France, 59 percent of 1008 urinary *P. mirabilis* isolates were resistant to amoxicillin, 48 percent were resistant to piperacillin, 34 percent were resistant to amoxicillin-clavulanate, and 2.8 percent were resistant to piperacillin-tazobactam.[41] One third of isolates were resistant to trimethoprim-sulfamethoxazole.[41] In Japan, extended-spectrum β-lactamase production in *P. mirabilis* went up from 7 percent in 2000 to 12.9 percent in 2009.[48] A report from China details the combination of carbapenem resistance and quinolone resistance in 19 isolates; all of them had the *Klebsiella pneumoniae* carbapenemase-2 gene.[29] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[46] In one study, amikacin retained better activity than did other aminoglycosides.[41] Most *P. mirabilis* urinary tract infections respond to ampicillin, but some organisms have been shown to acquire a plasmid-mediated β-lactamase.[42] Failure to clear bacteria should alert the physician to the possibility of urolithiasis or structural abnormality; removal of stones or surgical correction of anatomic defects often is required for cure.

CHAPTER 108

Providencia

Randall G. Fisher

The genus *Providencia* comprises pathogens most commonly associated with urinary tract infection. *Providencia* spp. are encountered most often as pathogens in hospitals or long-term care facilities and can be responsible for outbreaks of multidrug-resistant infection.[40]

BACTERIOLOGY

Providencia spp. (named after the city of Providence, Rhode Island) are motile gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine.[8,31] The genus distinguishes "urease-negative" organisms, *P. rettgeri*, *P. stuartii*, *P. alcalifaciens*, *P. rustigianii*, and *P. heimbachae*, from the otherwise biochemically similar "urease-positive" *Proteus* spp.[15,31] Urease is produced by most strains of *P. rettgeri* and by 15 percent or less of *P. stuartii* strains.[27] *Providencia* spp. also differ from other Proteeae in their ability to produce acid from inositol. Strains are differentiated further by reactivity with straight-chain hydroxy alcohols.[31] For a detailed discussion of taxonomy and characterization of *Providencia* spp., the reader is referred to the review by O'Hara and colleagues.[28]

EPIDEMIOLOGY

Providencia organisms are recovered uncommonly from stool in healthy humans, but they frequently colonize indwelling or condom urinary catheters, particularly in patients receiving antibiotic therapy.[5,10,16,40,41] In a Japanese study of patients with traveler's diarrhea, *Providencia* spp. were recovered, using a new selective medium, from 23 of 130 specimens tested.[42] *Providencia* spp. have been recognized as pathogens for more than 50 years[7]; *P. rettgeri* and *P. stuartii* are the most common species implicated in urinary tract infection.[10,12,13,24,41] Multiple biotypes of *P. stuartii* have been identified in hospital outbreaks, indicating the probability of multiple sources of colonization.[2] Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analysis of outbreaks.[33]

PATHOPHYSIOLOGY

P. stuartii does not seem to have greater access to the urinary tract compared with other bacteria; in patients with long-term catheters, the incidence of bacteriuria caused by this organism is equivalent to that caused by other uropathogens.[40] Rather, *P. stuartii* manifests an extraordinary ability to persist within the catheterized urinary tract.[41] Bacteriuria may take weeks to months to clear. A mannose-resistant, *Klebsiella*-like hemagglutinin may play an important role in the persistence and adherence of *P. stuartii* to urinary tract catheters.[26]

Despite the similarities between *P. mirabilis* (the major pathogen responsible for urolithiasis in children)[4] and urease-producing *Providencia* spp., the latter organisms rarely are associated with formation of stones. *P. stuartii* occasionally produces urease with a higher affinity for substrate, but *P. mirabilis* ureases hydrolyze urea 6 to 25 times faster.[14] Restriction-enzyme analysis of genes coding for the respective enzymes shows significant divergence.[14] These differences may explain the more frequent association of *P. mirabilis* with formation of stones.

Some strains of *P. alcalifaciens* have been isolated more commonly in children with diarrhea, and enteropathogenicity has been shown in HEp-2 cells and a rabbit model.[2,3] In vitro, *P. alcalifaciens* prefers basolateral to apical entry into Caco-2 cells; they are taken up by endocytosis and appear to require an invasion.[23] Ex vivo *P. alcalifaciens* strains show the ability to translocate and to resist complement-mediated lysis.[39] In children with diarrhea, *P. alcalifaciens* often is associated with other enteric pathogens, so its role in pathogenesis remains unclear.[1]

CLINICAL MANIFESTATIONS

Although *Escherichia coli* and *Proteus* spp. account for most urinary tract infections in children, *Providencia* spp. have been reported as a cause of infection in children with spinal injury and long-term urinary tract catheterization.[17,24] Most infections have been described, however, in elderly patients or adults with spinal injury who require long-term urinary tract catheterization.[40] Clinical findings are typical of those associated with urinary tract infection. Bacteremia is uncommon but devastating.[18] In a study of 132 cases of bacteremia caused by members of the tribe Proteeae, only 8 were caused by *Providencia* spp., but four of those patients died of the infection.[18] A single case of endocarditis and a case of relapsing pericarditis both caused by *P. stuartii* have been reported.[19,35]

Eye infections caused by *P. rettgeri*, including conjunctivitis, dacryocystitis, keratitis, and endophthalmitis, have been reported. These infections generally occurred in patients with compromise in ocular surface or in immunity.[29]

Providencia spp. have been implicated in the so-called purple urine bag syndrome, in which an enzyme from the organism causes 3-indoxyl sulfate to be formed, which discolors the urine blue or blue-violet. This syndrome usually occurs in patients with indwelling cystotomy or nephrostomy tubes.[20,38] Xanthogranulomatous pyelonephritis with a nephrocutaneous fistula has also been reported.[21]

Although central nervous system infection with *Providencia* spp. is extremely rare, meningitis occurred after a neurosurgical procedure in a patient in Turkey[36] and a left frontal lobe cystic mass was reported that was originally thought to be a tumor but proved to be a brain abscess caused by *P. stuartii*.[27]

DIAGNOSIS

Infection with *Providencia* spp. should be suspected when indole-positive, urease-negative, gram-negative rods, which oxidatively deaminate tryptophan, are isolated in culture. Because patients with long-term catheterization may be colonized with multiple organisms, *Providencia* spp. frequently are overlooked or misidentified.[7] Clinical laboratories should be encouraged to identify all bacterial colonies in patients with long-term catheterization in whom infection is suspected. Identification is particularly important because of the marked differences in susceptibility of uropathogens.[32]

TREATMENT

Empirical therapy should be guided by antimicrobial susceptibility testing of the patient's isolate and knowledge of susceptibilities of previously identified *Providencia* within the care facility. Removal of urinary tract catheters speeds eradication of these pathogens. Strains of *P. stuartii* and *P. rettgeri* commonly are resistant to many antibiotics. In a longitudinal Italian study of 223 *P. stuartii* isolates, 116 (52%) were extended-spectrum β-lactamase positive.[37] The rate of extended-spectrum β-lactamase–positive isolates increased from 31 percent in 1999 to 62 percent in 2002.[31] Since the 1970s, multidrug resistance has emerged[30,34]; many strains are resistant to sulfonamides, trimethoprim, nitrofurantoin, nalidixic acid, penicillins, cephalosporins, and aminoglycosides; some singular strains are resistant to most antibiotics in common use.[32] Imipenem-resistant strains have now been

described.[34] One case report describes an isolate that carried *blaPER-1*, *blaVIM-2*, and *armA* (a 16S methylase gene that confers resistance to aminoglycosides).[22] Much of the observed resistance seems to be plasmid based[11]; quinolones and aztreonam have shown some promise in the treatment of such cases.[6,9] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[25] Organisms that are resistant to gentamicin and tobramycin may remain susceptible to amikacin.

CHAPTER 109

Shigella

Theresa J. Ochoa • Margaret Kosek

HISTORICAL BACKGROUND

The term *dysentery* classically has been used to describe the frequent, painful passage of stools containing blood and mucus. The syndrome has been recognized since the time of Hippocrates. The differentiation of dysentery into bacillary and amebic forms followed the recognition by Shiga in 1898 that one form of dysentery was associated with a bacterium in the stools of affected individuals; their sera also were found to agglutinate the bacillus. In recognition of Shiga's achievement, the genus was eventually named after him.

The most important subsequent advance has been the recognition of the molecular basis of *Shigella* virulence. In the 1960s, researchers showed that shigellae invade the corneal epithelium of guinea pigs and cause keratoconjunctivitis (Sereny test). Subsequently, Formal and colleagues[85] showed that *Shigella flexneri* invades the intestinal epithelium. Since 1980, Sansonetti and colleagues[231,233] and other investigators[235] have identified multiple plasmid and chromosomal virulence genes.

BACTERIOLOGY

Shigellae are small, nonencapsulated gram-negative rods that are members of the Enterobacteriaceae. Technically, they are *Escherichia coli*, but for reasons of tradition and clinical usefulness, the designation as a separate genus has been preserved. Shigellae do not ferment lactose or do so slowly and are nonmotile (they lack the H [flagellar] antigen). They lack urease and do not produce hydrogen sulfide on triple sugar iron media or gas during metabolism of carbohydrate.[78] The somatic antigen (or O antigen) side chains that determine serotype and serogroup are attached as multiple repeating units to the lipid A core and core oligosaccharides shared with other members of Enterobacteriaceae. Envelope or K antigens that are heat labile also have been described, although their clinical relevance is uncertain.

Serogroup Classification

Four serogroups, or species, of *Shigella* are defined on the basis of serologic similarities and biochemical reactions. Group A *(Shigella dysenteriae)*, mannitol nonfermenters, includes 13 serotypes having O antigens that do not cross react immunologically. Two additional provisional serovars, types 14 and 15, also are pathogenic.[11] Serogroup D *(Shigella sonnei)*, ornithine decarboxylase–positive, slow lactose fermenters, share the same lipopolysaccharide. *Shigella* strains that ferment mannitol (in contrast to *S. dysenteriae*) but do not decarboxylate ornithine or ferment lactose (in contrast to *S. sonnei*) are

classified as serogroups B and C. Of these, the strains that express lipopolysaccharides that are related to each other immunologically are group B *(Shigella flexneri)*, whereas the strains whose O antigens are unrelated to each other or to other shigellae are group C *(Shigella boydii)*. Multiple serotypes of *S. flexneri* (15 serotypes and subtypes) and of *S. boydii* (18 serotypes) exist.

EPIDEMIOLOGY

Based on the findings of the Child Health Epidemiology Reference Group (CHERG) of the World Health Organization (WHO), it is estimated that globally 89 million community cases and 37 million outpatient cases of shigellosis occur annually in children younger than age 5 years.[140] Most of these cases occur in developing countries. In 1999, a review of the literature for 1966 through 1997 suggested that around 1.1 million persons die annually of shigellosis, including around 880,000 in Asia.[134] A recent review of the literature for 1990 through 2009 indicates that around 125 million shigellosis cases occur annually in Asia, of which 14,000 are fatal.[28] This estimate for illnesses is similar to the earlier estimate, but the number of deaths is 98 percent lower. The lower estimate of deaths is associated with markedly reduced case-fatality rates rather than fewer cases.

Generally, *Shigella* spp. are associated with 5 to 10 percent of all diarrhea cases and 30 percent of dysentery cases.[183] Although epidemic *Shigella* dysentery is the most dramatic manifestation of *Shigella* infections in developing countries, most infections are caused by endemic shigellosis. Despite the fact that severe dehydration usually is not seen in shigellosis, shigellosis is disproportionately represented in severe and fatal cases of diarrhea, particularly in children younger than 5 years old. The incidence of *Shigella* is increased by undernutrition,[131] and *Shigella* is one of the enteric infections that has shown to be most strongly correlated with linear growth deficits after infection.[41] *Shigella* is a common cause of prolonged and persistent episodes of diarrhea, and the dominant cause of the clinical dysentery syndrome in populations living in poverty or exposed to conditions where hygiene and water quality are suboptimal. Therefore, the empirical management of dysentery should always include an antibiotic that has been demonstrated to have low local levels of resistance.

According to surveillance reports of the Centers for Disease Control and Prevention, 10,000 to 15,000 cases of shigellosis have been documented each year during the past 30 years in the United States,[57] and it is currently estimated that nearly 500,000 cases occur annually in the United States, one fourth of which are domestically acquired.[236] *Shigella* is the third most important Foodborne Diseases Active Surveillance Network pathogen in 10 sentinel states in the United States, with a population-based incidence of 3.99 per 100,000 population. However, incidence rates have decreased significantly in 2009 when compared with rates documented in 1996 and 1998 (55% decrease).[58]

Because shigellae are spread through a fecal-oral route, they are especially prevalent where hygiene is poor. The organisms can be cultured from around toilets in homes where shigellae have caused disease. Toilet paper does not prevent contamination of fingers. Shigellae are transmitted easily from person to person because the inoculum size required to cause disease is only 10 organisms in the case of *S. dysenteriae* serotype 1[74] and a few hundred organisms in the cases of *S. sonnei* and *S. flexneri*.[72] Hand washing and wearing gloves are mandatory procedures for individuals caring for patients with bacillary dysentery. Patients who lack the acid barrier provided by a normally functioning stomach because of prior gastrectomy or use of antacids are at increased risk for acquiring infection.

Epidemics usually are associated with exposure to contaminated water or food, although as might be predicted from the inoculum size, outbreaks related to swimming also occur.[156] Houseflies can be mechanical vectors of shigellosis, particularly where the fly population is large. *Shigella* infection shows seasonal variation. In North America, few cases occur in the winter, whereas in tropical regions, the peak is during the rainy season. Shigellae are worldwide and thrive where susceptible individuals are grouped together (including institutions for retarded or mentally ill individuals, prisoner-of-war camps, Indian reservations, the military, daycare centers, and the developing world).[125,206,249] The devastating impact of *S. dysenteriae* type 1 epidemics in vulnerable concentrated populations is still notable as can be seen in refugee camps in Goma and Tanzania in the 1990s where attack rates ranged from 6.3 to 39.1 percent and case-fatality rates were estimated to be as high as 9 percent at some camps.[92,124]

The species of *Shigella* causing most infections varies according to regions. In developed countries, *S. sonnei* is the most common species, followed by *S. flexneri* (approximately 70% *S. sonnei* and 25% *S. flexneri*); however, in the developing world, this pattern is reversed, with *S. flexneri* being more common than *S. sonnei*. *S. dysenteriae* serotype 1 occurs primarily in Africa, India, and Bangladesh. *S. boydii* is found primarily on the Indian subcontinent.[185] However, *Shigella* has shown temporal procession in serogroup dominance. Recently, epidemiologic transition has favored the emergence of *S. sonnei* as the dominant serogroup in some countries (i.e., Israel, Argentina, Vietnam), although the reason for this is not clear.[130] A large molecular epidemiology investigation in China has provided convincing evidence for numerous serotype switching events, as well as changing antibiotic resistance, of an emergent sequence type that has replaced *S. flexneri* 2a as the dominant serotype.[265]

Humans and other primates can be infected with shigellae, and an age-related risk for acquiring symptomatic shigellosis exists. In contrast to *Salmonella* spp., which causes disease most frequently in the first few months of life, shigellae infrequently cause illness in the first 6 months of life. The peak incidence occurs in children between 1 and 4 years of age, with fewer cases occurring in children aged 5 to 9 years old. Adults are at lower risk.

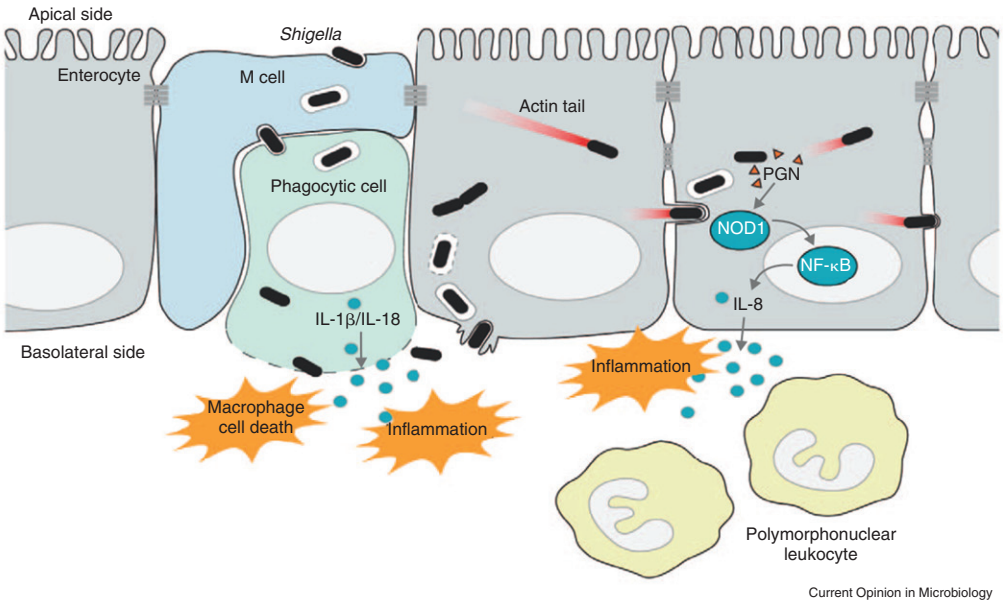

FIGURE 109-1 ■ Cellular pathogenesis of *Shigella* spp. *Shigella* passes the epithelial cells barrier by transcytosis through M cells and encounters resident macrophages. The bacteria evade degradation in macrophages by inducing an apoptosis-like cell death, which is accompanied by proinflammatory signaling. Free bacteria invade the epithelial cells from the basolateral side, move into the cytoplasm by vectorial actin polymerization, and spread to adjacent cells. Proinflammatory signaling by macrophages and epithelial cells further activates the innate immune response and attracts polymorphonuclear leukocytes. (See companion website on Expert Consult for a color version of this figure.) (From Ashida H, Ogawa M, Kim M, et al. *Shigella* deploy multiple countermeasures against host innate immune responses. *Curr Opin Microbiol* 2011;**14**:16-23.)

PATHOGENESIS

Invasiveness and Toxin Production

The ability to invade mammalian cells is the most important virulence trait of *Shigella* spp.* Uptake by M cells overlying Peyer patches with ingestion by macrophages under the M cells induces production of cytokines and recruitment of polymorphonuclear leukocytes (Fig. 109-1). Apoptosis is induced in macrophages after ingestion of shigellae; these events are accompanied by release of interleukin (IL)-1, IL-1β, and IL-18, which triggers other inflammatory events.[233,272,274] Polymorphonuclear leukocytes enter the gut lumen by moving between epithelial cells. The gaps between epithelial cells may be the portal of entry of bacteria into the epithelium. After penetration of intestinal epithelial cells, shigellae are located in vacuoles derived from the cytoplasmic membrane of the mucosal cells. The bacteria lyse these vacuoles, move intracellularly, multiply, kill the epithelial cells, and infect adjacent cells. Cell death is followed by formation of ulcerations and microabscesses in the colon. In contrast to *Salmonella* infection, *Shigella* infection rarely spreads beyond the lamina propria, so bacteremia and metastatic infections are uncommon.

The genetic basis of virulence has been studied extensively.[192,196] Invasiveness is the result primarily of genes on a large virulence plasmid (200 kb), containing a mosaic of around 100 genes and insertion sequences.† These genes encode a molecular apparatus called a type III secretion system (TTSS) that is capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.[196] More than 30 effector proteins of the TTSS have been identified and their virulence function and phenotype described.[191,237] Recent structural and functional studies suggest that two different sets of effectors are involved in inducing actin cytoskeleton reorganization to promote entry of bacteria into epithelial cells and in modulating cell signaling pathways to dampen innate immune responses induced on infection, respectively. Effectors involved in entry are produced independently of the TTSS activity, whereas effectors involved in controlling the cell responses are produced on activation of the TTSS.[197] The invasive plasmid antigen (ipa) region includes genes for four polypeptides needed for invasion: *ipaA*, *ipaB*, *ipaC*, and *ipaD*. The proteins produced by these loci are recognized by the humoral immune system. The product of the *ipaB* locus is essential for induction of apoptosis in macrophages.[273] The IpaH protein family has E3 ubiquitin ligase activity.[219] The mxi-spa region of the virulence plasmid is necessary for orientation of the ipa-encoded proteins into the outer membrane of the bacteria. The *virG* gene encodes a protein that causes intracellular and intercellular spread of shigellae after invasion of epithelial cells. The *virF* gene regulates a locus *(virB)* that is responsible for positive regulation of the ipa genes.[223]

Chromosomal loci regulate expression of the virulence plasmid.[195] The keratoconjunctivitis provocation *(kcpA)*

*References 90, 139, 147, 180, 190, 237.
†References 98, 99, 104, 230-232, 235, 237.

gene is a positive regulator of the *virG* virulence plasmid gene that determines ability to spread within and between cells. Lipopolysaccharides play a role in resistance to nonspecific host defense mechanisms that are encountered during invasion of tissue. The *Shigella* lipopolysaccharides induce the trafficking of Toll-like receptor 4, the dominant mediator of the innate immune response.[52] Smooth colonies express the complete complex of lipopolysaccharide O side chains required for full virulence—the ability to invade epithelial cells, to multiply within them, and to resist phagocytosis.[94,193] Rough colonial variants that lack complete lipopolysaccharides do not penetrate epithelial cells efficiently and are avirulent.

Some strains of *Shigella* spp. produce toxins that injure mammalian cells. A chromosomal locus in *S. dysenteriae* serotype 1 encodes a protein synthesis–inhibiting exotoxin (Shiga toxin) that is a major virulence factor in this serotype (and in the enterohemorrhagic *E. coli* serotypes that have the same or closely related genes).[31,242] This toxin is composed of a single copy of an A subunit (32,000 daltons) that is linked to five copies of B subunits (7,790 daltons).[187] The B subunits bind to a glycolipid cell receptor, globotriaosylceramide, followed by internalization. The A subunit cleaves an adenine residue from the eukaryotic 28S ribosomal subunit. The resulting block in elongation factor 1–dependent binding of aminoacyl tRNA to the ribosome causes cell death through inhibition of protein synthesis.[187] Shiga toxin previously was considered to be a neurotoxin because its administration to mice or rabbits caused paralysis and death[46,56,107]; it now is thought to target primarily the vascular endothelium. It causes fluid accumulation in rabbit ileal loops[80,126] that probably is related to reduced fluid uptake by damaged villus cells.

The severity of *S. dysenteriae* serotype 1 infection relative to other *Shigella* serotypes is thought to be caused by production of Shiga toxin. Enterohemorrhagic *E. coli* serotypes, such as *E. coli* O157:H7, produce an identical (Shiga toxin 1) or similar (Shiga toxin 2) toxin and, similar to *S. dysenteriae* serotype 1, cause bloody diarrhea and hemolytic-uremic syndrome. Enteroinvasive *E. coli* serotypes do not produce these toxins.[64]

Shigella spp. also produce two enterotoxins, ShET-1 and ShET-2.[257] All *S. flexneri* 2a strains produce ShET-1, whereas only 3.3 percent of other *Shigella* serotypes and no enteroinvasive *E. coli* serotypes possess the gene for this toxin.[184] ShET-2 is produced by all *Shigella* spp.[257] Genes of an additional toxin, designated *Shigella* enterotoxin, or Sen, have been found in 75 percent of enteroinvasive *E. coli* serotypes and 83 percent of *Shigella* strains.[177] These enterotoxins may contribute to the high-volume, watery diarrhea often seen in the initial stages of the disease.[23] Vaccine studies using a mutant with deletions of these toxin genes have shown that one or both enterotoxins play a role in human disease.[133]

Immune Response

Serum IgG, IgM, and IgA responses occur to the lipopolysaccharide and invasion plasmid antigens of shigellae.[189] Secretory IgA specific to both of these sets of antigens occurs in human milk and feces.[65] Protection is thought to be serotype specific. The level of IgG antibodies to lipopolysaccharides present in an individual before infection occurs determines whether symptomatic shigellosis develops.[69] No clear proof currently exists about the role of antibodies to the invasion plasmid virulence proteins or to the toxins. Cell-mediated immunity against shigellae also may play a role in resolution of infection. Production of αβ T cells and natural killer cells mediates interferon-γ production that may be essential to defense from *Shigella*.[142,262] Antibody-dependent cellular cytotoxicity against shigellae has been shown.

During infection, shigellae use several effectors to direct various cellular signaling pathways and to modify the innate immune activation of the host.[192,202] Several bacterial components such as lipopolysaccharides, peptidoglycan, and effector proteins delivered via the TTSS (i.e., rod protein)[168] are recognized as pathogen-associated molecular patterns (PAMPs) by Nod-like receptors (NLRs), including NOD1, NOD2, NLRP3 (NALP3), and NLRC4 (Ipaf), which stimulate an array of host innate immune systems that leads to the production of proinflammatory cytokines, chemokines, and antimicrobial peptides.[14,15] In addition, the remnants of the host cell membrane that result from the disruption of the phagocytic vacuolar membrane may also stimulate inflammatory responses.[75] All this causes activation of the nuclear factor κB and other terminal kinase pathways, with IL-8 appearing as a major chemokine mediating the inflammatory burst that is dominated by massive infiltration of the mucosa by polymorphonuclear leukocytes.[202] The levels of cytokines tumor necrosis factor-α, IL-1β, IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor in stool correlate with the severity of shigellosis. In contrast to other cytokines, interferon-γ and its receptor[214] are depressed early and increase during recovery. Fecal concentrations of tumor necrosis factor-α, IL-1β, IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor are significantly higher in patients with *S. dysenteriae* serotype 1 than in patients with *S. flexneri* infection.[216] Elevated tumor necrosis factor-α and IL-6 levels in stool and serum have been associated with complications during infection with *S. dysenteriae* serotype 1.[240] Infiltration of polymorphonuclear leukocytes and lymphocytes into the intestine is controlled by these cytokines. Epithelial cell production of IL-8 and a low ratio of IL-1RA to IL-1 are responsible for the severe inflammation.[13,229] T lymphocytes with suppressor-cytotoxic and helper-inducer phenotypes are recruited into the epithelium and lamina propria during infection with *Shigella*, related partly to the induction of HLA-DR expression in the rectal mucosa.[215] Peripheral blood lymphocytes of infected individuals respond to *Shigella* antigens in vitro with production of interferon-γ and IL-10.[192,228] The delivery of as yet uncharacterized TTSS-secreted proteins enables *Shigella* to suppress the transcription of genes that encode antimicrobial peptides, which promotes the advance of bacteria deeper into the crypts in the intestine.[245]

Shigella spp. elicit an inflammatory response during multiplication within macrophages and epithelial cells.

Shigella multiplication in macrophage cytoplasm induces cell death, which is achieved by two distinctive pathways: activation of caspase-1 by IpaB secreted by the TTSS and translocation of lipid A from the cytosol, which occurs independent of caspase-1 and Toll-like receptor 4 activities. Recent studies have characterized *Shigella*-induced macrophage cell death as pyroptosis or pyronecrosis, which is accompanied by severe inflammation.[14]

PATHOLOGY

The main morphologic changes of shigellosis (superficial ulcerations, focal hemorrhages, mucosal edema, erythema, and friability) occur in the colon where the organisms invade.[111,243] The rectosigmoid and distal segments of the colon typically are involved more severely than is the proximal colon. The epithelial cell damage may cause development of a pseudomembrane composed of thick, fibropurulent exudate tightly adherent to the necrotic ulcerated colonic mucosa. Pseudopolyposis also has been reported.[48] On microscopic examination, damage to epithelial cells, ulcerations, goblet cell depletion, and intense polymorphonuclear and mononuclear infiltration with crypt abscesses are seen. Rectal mucosa shows increased numbers of $CD8^+$ and $\gamma\delta^+$ T cells.[110] Vessels in the lamina propria are congested or thrombosed. Perforation of the colon usually does not occur as part of the colitis.[27] Evidence of inflammation and proinflammatory cytokines persists for at least 1 month after clinical resolution.[213] Histologic changes generally are more severe and persistent[96] with *S. dysenteriae* than with *S. flexneri*.[10]

CLINICAL MANIFESTATIONS

The incubation period ranges from 12 hours to a few days (if a low number of organisms is ingested). Onset of high fever, toxicity, and crampy abdominal pain is sudden. During the first 48 hours, high-volume watery diarrhea may occur (small bowel phase of disease); subsequently, low-volume, bloody, and mucous diarrhea develops in association with urgency and tenesmus (large bowel or "dysenteric" disease). In some cases, the watery diarrhea persists for several days without subsequent development of dysentery. Other children may have bloody or mucous diarrhea.

Physical examination shows fever, signs of toxicity, tenderness over the lower abdominal quadrants, and hyperactive bowel sounds. Signs of dehydration may be present. Rectal examination reveals severe tenderness. Rectal prolapse may be present, particularly when diarrhea is associated with malnutrition.

The course without therapy typically lasts 7 to 10 days. Although it is true that many enteric infections exacerbate undernutrition, initiating a "viscous cycle" of diarrhea and undernutrition, *Shigella* infections are particularly likely to do so. *Shigella* incidence is increased in underweight children.[131] *Shigella* causes a severe protein-losing enteropathy[42] (which is lessened by early appropriate antibiotic therapy)[38] and wasting of large amounts of vitamin A and zinc.[55,170] Shigellosis is associated with prolonged and persistent illness and linear growth shortfalls in children.[41]

TABLE 109-1 **Complications of Shigellosis**

Abdominal
Persistent diarrhea
Postdysenteric irritable bowel syndrome
Ileus, toxic megacolon, intestinal perforation
Protein-losing enteropathy, malnutrition
Surgical complications: intestinal perforation and obstruction, appendicitis, intra-abdominal abscesses
Neurologic
Seizures
Headache, lethargy, disorientation, hallucinations
Coma
Severe toxin encephalopathy or ekiri syndrome
Bacteremia
In malnourished children, young infants, and AIDS patients
Hemolytic-Uremic Syndrome
Only with *Shigella dysenteriae* serotype 1
Urogenital
Vulvovaginitis, urinary tract infections
Other
Conjunctivitis, keratitis, corneal ulcers
Reactive arthritis
Reiter syndrome
Hepatitis
Myocarditis

The need for surgical intervention in shigellosis is rare but is associated with significant morbidity and mortality. In a series of 57 children with complications of shigellosis requiring surgical intervention,[169] intestinal obstruction (53%), appendicitis (28%), and colonic perforation (17%) were the most common occurrences (Table 109-1).

Although the organism usually is excreted for only a few days or weeks (range, 1 to 30 days), carriage of the organism for many months sometimes occurs.[67,148] The illness usually is acute; a chronic carrier state can occur in malnourished individuals. Asymptomatic infection of toddlers living in an endemic area occurs commonly and is usually transient, lasting no more than a few days.

Extraintestinal Manifestations and Complications

Multiple extraintestinal complications have been described with *Shigella* infection (see Table 109-1). Seizures have been reported in 10 to 45 percent of hospitalized children with culture-proven shigellosis.[21,25,30,71,83] In outpatient settings, the frequency of seizures is very low. Children who develop neurologic complaints may have lethargy, severe headache, disorientation, hallucinations, or self-limited convulsions lasting less than 15 minutes.[19,22,25,174] Seizures are most likely to occur in very young patients, patients with a high peak body temperature, and patients with a family history of convulsive disorders.[21,135] Seizures can be focal, although usually they are generalized.

When symptoms related to the nervous system occur, they are likely to appear early in the illness, even preceding development of diarrhea. Death rarely has been described[106]; most children recover completely with no residual neurologic deficits.[22] In contrast, in Bangladesh, where seizures in shigellosis typically are associated with factors known to alter consciousness (e.g., hypoglycemia, hyponatremia, fever), mortality rates are high.[129] Children with *Shigella* encephalopathy have significantly higher case-fatality rates than children with shigellosis without encephalopathy.[60] The pathogenesis of neurologic signs and symptoms during episodes of shigellosis is unclear. Hypoglycemia and electrolyte abnormalities are found in a few patients.[22] Direct invasion of the central nervous system during *Shigella* bacteremia is very rare.[263] Simple febrile seizures might explain convulsions in a few children with dysentery, but some children who have seizures during episodes of shigellosis do not experience seizures during other febrile infections and are outside the age range usually associated with febrile seizures.[22] Shiga toxin formerly was thought to cause the neurologic symptoms because it was considered to be a neurotoxin; however, data now clearly show that Shiga toxin is not responsible.[20] In an animal model of *Shigella*-related seizures, corticotropin-releasing hormone, a stress neurohormone, was associated with increased susceptibility to seizures after exposure to *S. dysenteriae*.[268] Work from the same group has demonstrated that proinflammatory mediators are involved in *Shigella*-related seizures[267]; however, these researchers found that prostaglandins, which are host mediators induced during the inflammatory process, are not involved in the enhanced seizure response after exposure to *Shigella*.[269]

Severe toxic encephalopathy has been described. This syndrome (ekiri), as originally described in Japan, was characterized by dysentery with hyperpyrexia, convulsions, sensory disturbances, and rapid progression to death.[224] The children died of cerebral edema early in the course of disease (6 to 48 hours after onset). Mild hyponatremia has been a common finding.[93] Children with ekiri did not have sepsis, disseminated intravascular coagulation, hemolytic-uremic syndrome, or severe dehydration. This toxic encephalopathy is rare. Whether this syndrome is part of a continuum of central nervous system dysfunctions with seizures and other encephalopathic symptoms or has a completely different pathogenesis is unclear.

Hemolytic-uremic syndrome (microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure) or isolated hemolysis has been reported, mainly after infections with *S. dysenteriae* serotype 1 and rarely after infection with *S. flexneri*.[211] Vascular endothelial cell damage by Shiga toxin is considered to be the initial event, although endotoxin absorbed from the gut also may play a role.[132]

Ileus that progresses to toxic megacolon with distended loops and eventual intestinal perforation occurs.[26] It is seen mainly with *S. dysenteriae* serotype 1 infection.

Septicemia in shigellosis is a rare occurrence except in human immunodeficiency virus (HIV)-infected patients, malnourished children, young infants, and children with *S. dysenteriae* serotype 1 infections.[100,123,164,238] The mortality rate is at least twice as high in dysentery-associated sepsis as in shigellosis uncomplicated by bacteremia. The serogroup-related mortality risk in cases of *Shigella* bacteremia has been reported to be 85 percent for infection with *S. dysenteriae*, 43 percent for infection with *S. flexneri*, and 25 percent for infection with *S. sonnei;* bacteremia rarely is reported with *S. boydii* infection.[161] In Bangladesh, *Shigella* bacteremia was found in 4 percent of patients.[250] When bacteremia occurs with dysentery, it is as likely to be caused by other enteric bacteria as by the *Shigella* itself. The occurrence of *Klebsiella*, *E. coli*, and other enteric pathogens in blood cultures of children with shigellosis presumably reflects loss of the barrier function during severe colitis.[179] *Shigella* bacteremia may be complicated by disseminated intravascular coagulation and multiorgan failure. Bronchopneumonia may develop in septicemic children,[5] but its pathogenesis is unclear. Children who die of shigellosis often have pneumonia at autopsy.[48] HIV-infected patients with systemic shigellosis are more likely to die than patients not infected with HIV.[123]

Other extraintestinal infections rarely are caused by *Shigella* spp. Vaginitis with a bloody discharge (sometimes lasting for months in the absence of specific therapy) may occur, usually without concurrent or recent diarrhea.[70,176] *Shigella* cystitis, not always associated with diarrhea, has been described, usually in girls.[30] Conjunctivitis, keratitis, corneal ulcers, and iritis are other uncommon manifestations of shigellosis that usually are assumed to occur after autoinoculation.[30,253] Hepatitis with mildly abnormal liver function test results has been described.[248] Myocarditis manifested clinically by hypotension despite fluid replacement, arrhythmia, heart block, or low voltage on electrocardiography and pathologically by interstitial lymphocytic infiltrates and focal necrosis has been described.[221]

Postinfectious complications of shigellosis include reactive arthritis and postinfectious irritable bowel syndrome. Reactive arthritis may develop after infections with enteric pathogens such as *Shigella*, *Campylobacter*, *Salmonella*, or *Yersinia*.[53] However, the lack of a clear case definition precludes assessing the real disease burden of postinfectious arthritis. In general, reactive arthritis after shigellosis occurs especially in adults who are HLA-B27 positive; is uncommon in children[50]; and is unlikely to be associated with *Shigella* vaccines in developing countries.[88] Postdysenteric irritable bowel syndrome occurs in some patients after recovery.[261] In a recent case-control study of children in Italy, 43 percent of children with prior *Shigella* infections were found to have symptoms of postinfectious irritable bowel syndrome versus 11 percent of controls.[234] However, in a study conducted in the Netherlands the prevalence of postinfectious irritable bowel syndrome after *Campylobacter*, *Salmonella*, or *Shigella* infections was 9 percent.[97]

Shigellosis in the Neonatal Period

Bacillary dysentery is rare in neonates.[31,76,81,101,141] More than half of the reported neonatal cases occurred during the first 3 days of life, which is consistent with fecal-oral

transmission during delivery,[95,181] usually from a symptomatic mother. Although a neonate with shigellosis usually has only low-grade fever with diarrhea of variable severity,[6,137,172] septicemia[145,222] and chronic diarrhea are more common than in older children. Intestinal perforation has been reported in neonatal shigellosis.[247] Diarrhea more often is nonbloody in infants; fever also occurs less commonly than in older children.[109] Data on age-related mortality caused by shigellosis in developing countries suggest that the mortality rate of the neonate is more than twice that of older children.

Shigellosis in Acquired Immunodeficiency Syndrome

In patients with acquired immunodeficiency syndrome (AIDS), shigellosis not only is more common and more severe but also is associated more often with bacteremia.[32,108,123] In contrast to the usual short, self-limited course of shigellosis, *Shigella* infection in patients with AIDS may be chronic and relapsing, despite appropriate antibiotic treatment.[138,241]

LABORATORY FINDINGS

The fecal leukocyte examination is helpful in evaluating a patient with fever and watery diarrhea. Direct microscopic examination of fecal mucus stained with methylene blue shows many polymorphonuclear leukocytes in patients with colitis, including most patients with shigellosis.[103] The blood leukocyte count in patients with shigellosis often is normal, although leukopenia or leukocytosis may occur.[18] The differential of the blood leukocyte count typically shows an increased percentage of band forms. Approximately one third of children with shigellosis have more bands than segmented neutrophils in their peripheral blood smear. A leukemoid reaction, with a peripheral leukocyte count greater than 50,000/mm^3, has been reported, mainly with infections caused by *S. dysenteriae* serotype 1.[49] A leukemoid reaction has been reported in 10 percent of patients infected with the Shiga bacillus. When examination of cerebrospinal fluid is performed in children with neurologic symptoms, normal results usually are obtained, although some patients have a mild lymphocytic pleocytosis. Likewise, when electroencephalography is performed, the results usually are normal.[22]

DIAGNOSIS

Bacillary dysentery usually is suspected in children who present with bloody diarrhea, high fever, tenesmus, and generalized toxicity. Approximately half of children do not develop bloody diarrhea during the course of their disease. This fact is especially relevant in developed countries, where most infections are caused by *S. sonnei*. The presence of only watery diarrhea does not exclude the possibility of shigellosis in an ill patient with high fever.

Isolation Techniques

Proof of the diagnosis of suspected bacillary dysentery often is problematic. Definite diagnosis of *Shigella* infection depends on isolation of the organism from stool specimens or rectal swabs. The bacteria may not survive in fecal specimens during transit, however, and special selective media are necessary for isolation. Recovery of shigellae is easier early in the course of the disease than later because the number of viable organisms in stools decreases significantly during late stages of the disease. Even in adult volunteer studies, when appropriate stool cultures were obtained daily, cultures failed to isolate shigellae in approximately 20 percent of volunteers who had ingested the organism and developed diarrhea.

Several measures increase the likelihood of isolating *Shigella*. Specimens should be processed without delay. Pre-enrichment broth does not significantly impact isolation rates, and the main determinant of success in isolating *Shigella* is rapid processing time (time between voiding and storage in an appropriate transport medium) and minimal time to primary plating. If a specimen cannot be processed immediately, a transport medium, such as buffered glycerol saline or Cary-Blair, should be used. More than one stool culture or rectal swab should be obtained and inoculated promptly onto at least two different culture media. Specimens should be plated lightly onto MacConkey, xylose-lysine-deoxycholate, or Hektoen enteric agar, whereas a heavier plating is necessary for the more inhibitory *Shigella-Salmonella* medium.[173,252] After overnight incubation at 37° C, lactose-negative colonies are transferred to triple sugar iron and lysine iron agar slants and incubated again overnight. Slants showing characteristic reactions of alkaline red slants, acid butt, and production of gas are tested biochemically for presumptive identification and then serologically for definitive identification.

Other Diagnostic Methods

Because presumptive identification of *Shigella* takes at least 48 hours and definite identification takes approximately 72 hours, attempts to develop rapid diagnostic methods are being made, especially because institution of early treatment is important in shigellosis. Identification of shigellae by specific DNA probes with use of either restriction fragments or synthetic oligonucleotides[182] based on detecting virulence genes located on the 120- to 140-MDa plasmid has been described. Because the invasion plasmids of shigellae, similar to other plasmids, may be lost spontaneously, a DNA probe derived from *S. flexneri ipaH* gene, a multicopy element that is found on the chromosome and on the invasion plasmid of shigellae, has been developed and found to be more sensitive than the probes that were used previously.[258] Use of polymerase chain reaction (PCR) in vitro amplification of nucleic acids, to detect shigellae directly from stool specimens, has been reported.[86] PCR can detect as few as 10 colony-forming units of *S. flexneri* in stool specimens, whereas the sensitivities of DNA probe hybridization (with no amplification) and standard

biochemical methods are 10^3 and 10^6 colony-forming units, respectively. PCR for *ipaH* genes seems to be more sensitive than culture; 28 percent of patients with dysentery with a positive PCR assay result are culture negative.[89,113] Another new method for the identification of *Shigella* is microarray analysis using the *gyrB* genes.[118] This novel approach also renders it possible to identify simultaneously other enteric pathogens, such as *Salmonella* spp. and diarrheogenic *E. coli*.[118]

Serologic studies are not helpful in establishing the diagnosis of shigellosis in individual patients; humoral antibodies develop after clinical recovery. Serologic studies may be helpful, however, in epidemiologic studies to define the level of endemicity of shigellosis.

Sigmoidoscopy and barium enema study are unnecessary, unless they are indicated to rule out other conditions. When these procedures are performed in patients with a possibility of having shigellosis, caution is necessary because of the diffuse acute colitis and risk for perforation.

DIFFERENTIAL DIAGNOSIS

Colitis of any etiology manifesting as acute-onset bloody diarrhea with fever and abdominal cramps can mimic shigellosis. Etiologic agents to be considered include *Campylobacter* spp., *Salmonella* spp., *Clostridium difficile*, *Yersinia enterocolitica*, *Shigella* spp., *Vibrio parahaemolyticus*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli* (e.g., serotype O157:H7), *Balantidium coli*, and *Entamoeba histolytica*. The initial presentation of inflammatory bowel disease can mimic shigellosis.

An etiologic diagnosis of acute colitis syndrome on the basis of clinical presentation is difficult to make, although some data suggest a specific causative agent. In developed countries, *Campylobacter* is the most common cause of acute infectious colitis. Shigellosis should be suspected when evidence exists of person-to-person spread and when convulsions or other neurologic symptoms develop. A history of previous antibiotic treatment suggests diarrhea related to *C. difficile*, and previous consumption of seafood suggests *V. parahaemolyticus*. *Yersinia* infections are found mainly in the cooler regions of Europe and North America; the disease may mimic acute appendicitis because of the right lower quadrant pain associated with mesenteric lymphadenitis.

Enterohemorrhagic *E. coli* infection often causes bloody diarrhea with little or no fever, in contrast to shigellosis, in which high fever is typical. Negative stool cultures for the mentioned bacterial pathogens may suggest infection by enteroinvasive *E. coli*. Amebiasis causes a colitis similar to the colitis caused by *Shigella*,[244] although it is of slower onset, with a lower degree of fever; the findings on fecal leukocyte examination are negative. The involvement of the colon with amebiasis is less diffuse than in shigellosis; areas of normal mucosa are found between ulcerations.

A prolonged course with negative cultures should raise concern about the possible presence of either ulcerative colitis or Crohn disease. When watery diarrhea is present, the list of possible etiologic agents is even longer, although many agents that cause watery diarrhea are associated with little or no fever and are not often confused with shigellosis. The diagnosis usually cannot be made by clinical presentation alone and requires laboratory confirmation.

TREATMENT

Fluid Administration

Dehydration is less a problem with shigellosis than with rotavirus or toxigenic *E. coli* infection. Some children with shigellosis, particularly young infants, have dehydration during the course of the disease. The high-volume watery diarrhea seen early in the course of the disease may cause excess losses of fluids and electrolytes; likewise, in patients with severe colitis, systemic toxicity and vomiting may cause anorexia that interferes with fluid intake.

Assessment of the hydration status of the patient on admission is mandatory, with early institution of appropriate fluid and electrolyte therapy needed. Low osmolarity oral rehydration (total osmolarity 245 mOsm/L, 75 mEq sodium, 20 mEq potassium, 10 mmol/L citrate, 75 mmol/L glucose), an improved choice especially in undernourished children, should be administered when available. Oral rehydration with commercially available solutions (e.g., Pedialyte) also is acceptable, and continued feeding is to be encouraged whenever possible. Administration of intravenous fluid therapy is necessary in children who are comatose, have an ileus, or are in shock. Early (12 to 24 hours after oral fluids are begun) breast-feeding and age-appropriate feeding in these children is a priority, especially in undernourished patients. Children with severe disease, seizures, and/or obtundation should have glucose and serum sodium levels monitored because hyponatremia and hypoglycemia are treatable complications seen in severe disease and possibilities to consider in severe cases or in patients who decompensate while receiving appropriate antibiotic therapy.

Antibiotic Therapy

Children who have dysentery always should be treated empirically with antimicrobial agents. WHO guidelines suggest that presumptive shigellosis should be treated with antibiotics, the choice being decided by the antimicrobial susceptibility pattern of locally circulating *Shigella* strains (WHO/CDR/95.3). If after 2 days of therapy, the patient's condition improves, a full course of therapy for 5 days should be given. If the patient does not improve, the antibiotic should be changed. If after the second antibiotic the patient does not show signs of improvement, the diagnosis must be reviewed, and stool microscopy, culture, and susceptibility testing should be performed where available.[183]

Appropriate antimicrobial therapy for shigellosis shortens the duration of fever and diarrhea and reduces

TABLE 109-2 **Antibiotic Treatment of Shigellosis in Children**

Antibiotic	Dosage	Comments
Azithromycin	12 mg/kg/day once daily PO on day 1, followed by 6 mg/kg/day once daily on days 2-5 (maximum 500 mg/day)	Although published data in children are limited, its use is recommended by many experts.
Nalidixic acid	55 mg/kg/day PO divided every 6 hr (maximum 2 g/day)	Not available in the United States; contraindicated in infants <3 mo old. Rates of resistance are rapidly increasing in Southeast Asia.
Ciprofloxacin	15-30 mg/kg/day PO divided every 12 hr (maximum 1.5 g/day)	Rates of resistance are increasing in Southeast Asia.
Ceftriaxone	50 mg/kg/day IM or IV (maximum 2 g/day)	Current drug of choice for empirical therapy for severe dysentery in children
Pivmecillinam	80 mg/kg/day divided four times a day	
Meropenem	120 mg/kg/day IV divided three times a day	Option for severe disease in patients with drug-resistant or suspected drug-resistant strains (from Southeast Asia)
Cefixime	8 mg/kg/day PO divided every 12-24 hr (maximum 400 mg/day)	Not recommended as therapy in adults

IV, intravenously; PO, orally.

the risk for developing complications.[16] Shedding of the organisms in stools stops within 1 to 2 days, so that intrafamilial spread may be decreased. Therapy should be stopped or changed on the basis of culture results (e.g., another pathogen or a resistant *Shigella* strain is isolated) and clinical response.

The choice of antimicrobial agent is complicated by the increasing frequency of antibiotic resistance.[79,82,130,227] Organisms resistant to ampicillin, trimethoprim-sulfamethoxazole, tetracycline, and chloramphenicol have been reported from the Middle East,* Africa,† South America,[151,177,185,209] Europe,‡ Eurasia,[27,194,270] Asia,§ and the South Pacific. Currently, ampicillin and trimethoprim-sulfamethoxazole are inappropriate for empirical therapy; they should be used only if the organism has been shown to be susceptible.[16]

Multiresistant strains also are found commonly in some parts of the United States. Among 344 *Shigella* isolates, from 1999 to 2001, 95 percent were resistant to one or more antimicrobial agents and 70 percent were resistant to two or more agents.[204] Among 1118 *Shigella* strains isolated from the Foodborne Diseases Active Surveillance Network and National Antimicrobial Resistance Monitoring System during 2000 through 2010, 74 percent of strains were resistant to ampicillin, 36 percent to trimethoprim-sulfamethoxazole, 28 percent to tetracycline, 2 percent to nalidixic acid, and 0.5 percent to ciprofloxacin. However, antimicrobial resistance differed by race, ethnicity, age, travel, and species.[239]

Multiresistant *Shigella* spp. are particularly likely to emerge in individuals who are exposed to multiple antibiotics[251] (e.g., patients with AIDS) and individuals who recently have traveled to areas with known resistance. Likewise, children in daycare centers are at risk for acquiring resistant organisms because the frequent use of antibiotics for otitis media may favor selection and emergence of resistant enteric organisms and because crowded living conditions and poor hygiene facilitate transmission.[45]

Generally, shigellae are susceptible in vitro to azithromycin, ceftriaxone, cefotaxime, cefixime, nalidixic acid, and quinolones. However, resistance to these antibiotics is being reported in several regions. Nalidixic acid–resistant *Shigella* has rapidly developed principally in Asia and Africa.[62,96] Resistance to ciprofloxacin is increasingly common in India and in travelers returning from India.[167,246] These fluoroquinolone-resistant strains have mutations in *gyrA* and *parC* and have developed efflux pumps.[200] Resistance to ceftriaxone[158,260] and azithromycin has also been reported in some countries.[44]

In vitro susceptibility does not always predict clinical efficacy or superiority of one drug over another, however. The first-generation and second-generation cephalosporins are active in vitro but have been ineffective in clinical trials. Clinical studies have shown some drugs to be clearly superior to others when susceptibility data have suggested that either might work well.

Prevalent serotypes and resistance patterns vary from year to year in a given locale. Typically, rates of resistance are related to the severity of disease caused by a given serotype. The more likely an organism is to cause severe disease, the more likely that resistant strains will emerge. *S. dysenteriae* serotype 1 is more likely to be multiply resistant than *S. flexneri; S. flexneri* is more likely to be resistant than *S. sonnei*. In Africa[43,121] and Asia,[34,36,63,157,175] *Shigella dysenteriae* resistant to nalidixic acid and ciprofloxacin have been reported. Nalidixic acid–resistant *S. flexneri* also have been recognized occasionally.[62] Local resistance patterns, history of travel to an area of frequent resistance,[251] and severity of illness should determine treatment.

Given the frequent occurrence of resistant organisms, optimal empirical therapy in children with dysentery should include azithromycin, a third-generation cephalosporin, nalidixic acid, or ciprofloxacin (Table 109-2).*

Although less well studied, ampicillin-sulbactam and pivmecillinam also have been shown to be effective in children. In children, oral cefixime seems to be superior to ampicillin-sulbactam.[105] Adults do not respond well to usual doses of cefixime.[226]

Local resistance patterns, history of travel to an area of frequent resistance,[251] and severity of illness should determine treatment. In the absence of local susceptibility data, the WHO recommendations should be followed.[254,264] First-line therapy is ciprofloxacin (in all age groups, including children), and second-line therapy is pivmecillinam (where available), ceftriaxone, or azithromycin. Use of quinolones in children has been controversial. An oral fluoroquinolone (ciprofloxacin, norfloxacin) seems to be optimal for adults.* A considerable body of evidence from the long-term use of these drugs in children with cystic fibrosis has been accumulated as has evidence from short-term use to treat typhoid fever and dysentery in children[143]; no evidence of bone or joint toxicity or growth impairment has been found, except for transient musculoskeletal events (arthralgia) in some children.[1,220] Nalidixic acid does not cause arthropathy or limit growth when it is used for a short time.[186]

Data for children suggest that norfloxacin at a dose of 10 to 15 mg/kg/day or ciprofloxacin at a dose of 10 mg/kg every 12 hours (maximum, 500 mg/dose) for 5 days is effective therapy.[93,144,155,225] In adults, short-course therapy (1 or 2 days) with ciprofloxacin has been effective for treatment of infections caused by *Shigella* spp. other than *S. dysenteriae*, for which a 10-dose, 5-day regimen is superior.[37] Pediatric data suggest that even for *S. dysenteriae* serotype 1 a short course of ciprofloxacin 15 mg/kg/dose every 12 hours for 3 days is as effective as a 5-day course.[271]

Because the patterns of antibiotic resistance of shigellae change, susceptibility testing should be performed on all clinical isolates if facilities are available, and the treatment should be changed accordingly. The recommended duration of antibiotic therapy for shigellosis usually is 5 days. Studies in adults and children have shown, however, that short-course treatment is nearly as effective as multiple doses in terms of symptomatic improvement,[91,160] although eradication of the organism from stools is less likely to occur with a single-dose regimen.[116] Because a major goal of antibiotic therapy is to reduce person-to-person transmission, multiple doses are preferred.

After initiation of therapy, a resistant organism can be suspected in the event of persistence of fever, grossly bloody stools, or unchanged frequency of stools by day 3 of therapy.[112] Persistent presence of numerous fecal leukocytes (>50 per high-power field) and erythrocytes (>5 per high-power field) at day 5 also suggests resistance. These findings are important because morbidity and mortality rates are higher when the organism is not susceptible to the initial drug of choice.[117] Protein-losing enteropathy is a more likely occurrence with resistant *Shigella* spp. if an inadequate agent has been used.[38]

*References 17, 33, 39, 105, 144, 160, 208.

Adjunctive Therapy

As with other forms of infectious colitis, antimotility agents should be avoided. Antimotility drugs, such as diphenoxylate (Lomotil), prolong the duration of fever, diarrhea, and excretion of the organism.[73] It has been speculated that intestinal motility and the constant fluid flow are important host defense factors for clearing of the organism and recovery from the infection.

Nutritional therapy is a key in undernourished children living in poverty, where the burden of global *Shigella* infections is focused. A high-protein, high-calorie diet during convalescence is important, and children should receive at least one additional meal a day until pre-illness weight is achieved. Nutritional therapy based on green bananas, a food rich in amylase-resistant starches, has been shown to be more efficacious than diet therapy with rice- or yogurt-based therapies in different trials in Bangladesh and Venezuela.[9,210] Because this is an affordable staple in many regions where shigellosis is endemic, its adjunctive use should be considered. Zinc should be given to all children at 20 mg/day (dosed as elemental zinc with sulfate and gluconate preparations being equally efficacious) for 10 to 14 days in children older than the age of 6 months; younger children should receive 10 mg/day for the same duration.

PROGNOSIS

Most patients recover eventually with or without specific antimicrobial therapy, although illness may be prolonged and severe if it is not treated with appropriate antibiotics.[47] The mortality rate in developed countries is less than 1 percent, and life-threatening complications are rare events. With appropriate antibiotic therapy, defervescence usually occurs within 24 hours and the diarrhea decreases dramatically in 1 to 2 days. If left untreated, the disease usually lasts 1 week or more. In developing countries, childhood shigellosis is associated with significant morbidity and mortality (10% to 30%),[35] particularly if it is caused by *S. dysenteriae* serotype 1. Children with malnutrition are particularly likely to have a complicated course.[61] Shigellosis in malnourished children often causes a vicious cycle of further impaired nutrition, and repeated infections may be associated with impaired growth. Young infants and severely undernourished children are more likely to have bacteremia, which markedly increases mortality rates.[188]

PREVENTION

In developed countries where person-to-person transmission of shigellae is the major mode of infection, personal hygiene measures are most important.[128] Special attention to hygiene should be given in daycare centers, which sometimes play a central role in community-wide outbreaks of shigellosis.[171] The close contact among children too young to control their excretions renders this setting ideal for fecal-oral spread of the organism. Children attending daycare centers frequently transmit

infection to their families. Washing hands after defecating and before eating or preparing meals is important and helpful in preventing spread.[128] Daycare personnel who prepare food should avoid performing diaper-changing duties. Sick children should be excluded from the daycare center or cohorted, and mothers should be educated regarding the possibility of being infected by their children and the use of the necessary precautions. Proper cooking of potentially infected food, appropriate refrigeration, and exclusion of individuals with diarrhea from handling food are important precautions. Education of staff members in proper hygiene is essential to infection control.[205]

Patients with diarrhea in institutional and hospital settings should be isolated for prevention of outbreaks. Aggressive investigation and early initiation of appropriate antibiotic therapy in cases of bacillary dysentery are important measures in reducing excretion of virulent shigellae and stopping spread of the disease. Use of antibiotics for prophylaxis is not recommended.

In developing countries, a safe water supply and appropriate sanitation systems are important measures for reducing the risk for shigellosis. Chlorination of drinking water is important. Water stored in vessels that permit hand dipping has been defined as a risk factor.[256] Food prepared by street vendors also has been recognized as a risk factor. Prolonged breast-feeding is the best practical strategy for prevention of shigellosis (and most other enteric infections) in infants in most of the developing world.[4,66,165] Educational efforts to promote breast-feeding in these areas are key to children's survival. Human milk contains specific secretory IgA antibodies against *Shigella* lipopolysaccharides and virulence plasmid-coded antigens.[65] Lactoferrin and other nonspecific (nonantibody) factors in human milk, the effect of human milk on the type of intestinal flora, and the supply of an uncontaminated food source all may contribute to the protective effect of breast-feeding against diarrheal disease.

Natural clinical *Shigella* infection confers approximately 75 percent protection against illness on subsequent exposure to the homologous *Shigella* serotype and in some instances against heterologous serotypes. Antibodies (serum or mucosal) directed against the lipopolysaccharide O-antigen appear to play a major role in protection. The first line of defense, however, occurs at the mucosa.[198] Serotype-specific (lipopolysaccharide-based) vaccines have been produced.[84,85] Although early studies showed that immunization by the parenteral route with killed vaccines was ineffective, interest in this approach continues.[24,68,146] Several oral, live organism–based *Shigella* vaccines have been studied. Avirulent mutants of *S. flexneri* that lack the ability to invade the intestinal mucosa are safe and effective in monkeys. Multiple doses of large numbers of organisms were required to protect humans, however. Attenuated vaccines prepared from streptomycin-dependent mutant strains were effective but unstable.[166] Genetically attenuated *S. flexneri* strains conferred protection but caused diarrhea when fed to some volunteers. Prototype-attenuated *S. flexneri* strains CVD 1208[133] and WRSS[122] have provided encouraging results in early clinical trials. Two nonliving vaccine approaches include the oral administration of proteosomes[87] and of inactivated *Shigella* bacteria.

A recent trial of a new set of O-specific polysaccharide conjugate vaccines in Israeli children has demonstrated immunogenicity; however, there was no significant level of protection for the *S. sonnei* conjugate in children 1 to 2 years old, the age when *Shigella* infections peak in most endemic regions. Additionally, the incidence rates at the study site did not allow for estimates of the efficacy of the *S. flexneri* conjugate.[199] New studies are being conducted using improved techniques for enhancing immunogenicity of the polysaccharide unit and using synthetic conjugates.[203,218] Other new candidate vaccines are being evaluated, including the use of the major outer membrane proteins (OmpA) of *S. flexneri* 2a[207]; outer membrane vesicles (OMVs) from *S. flexneri*[51]; invasin-complex-based vaccines (Invaplex) from *S. flexneri* 2a containing lipopolysaccharides[217,255]; type III secretion system (TTSS) IpaB and IpaD proteins, which are more likely to be cross protective[162]; and second-generation *virG (iscA) S. sonnei* live attenuated candidate vaccines.[29,212]

No effective, licensed vaccine against shigellosis is available.* Whatever prototype *Shigella* vaccines prove to be well tolerated, immunogenic, and protective, the final formulation will have to confer protection against multiple epidemiologically important serotypes, including *S. dysenteriae* 1 (the cause of epidemic disease from Shiga toxin), all *S. flexneri* serotypes and subtypes (the most important agents of endemic disease in developing countries), and *S. sonnei* (responsible for 5% to 15% of shigellosis in developing countries and an important cause of traveler's shigellosis and of shigellosis in diarrhea in daycare centers in industrialized countries).[146]

CHAPTER 110

Serratia

Randall G. Fisher

Similar to other members of the Enterobacteriaceae, the genus *Serratia* contains species increasingly associated with opportunistic infection in the compromised host. One of the oldest bacterial organisms to be named,[116] *Serratia marcescens* is the chief species associated with disease in humans and has been associated with infection of the urinary tract, the respiratory tract, local wounds, and central venous catheters. Illness may be complicated by bacteremia and meningitis. Treatment of infection may be made exceptionally difficult because these organisms frequently are resistant to penicillins, cephalosporins, and aminoglycosides.

BACTERIOLOGY

S. marcescens can produce a red pigment resembling blood on contaminated foodstuffs. In the 6th century, the "miraculous" appearance of blood on food provoked superstition and scientific investigation. Troops were goaded into battle, and religious beliefs gained support because of the fortuitous growth of the saprophyte in bread.[116] In vitro, the red pigment produced by these strains (called "prodigiosin") is toxic to cancer cells but not to nonmalignant cell lines.[33] In addition, prodigiosin has activity against the mitochondria of *Trypanosoma cruzi*[44] and is also larvicidal against *Aedes aegypti*.[91]

In 1819, *S. marcescens* was named by Bizio, who correctly interpreted the discoloration of cornmeal to be due to a living organism.[76] The genus name honors the Italian physicist Serrafino Serrati, who Bizio thought had been slighted in favor of Robert Fulton as inventor of the steamboat; the species name *marcescens* was drawn from the Latin word meaning "to decay."

We now recognize the genus *Serratia* as comprising organisms that are straight, motile, catalase-positive, gram-negative rods. On solid agar, colonies are opaque; iridescent; and white, pink, or red. Organisms appear positive with the Voges-Proskauer test.[53] The genus may be distinguished from other Enterobacteriaceae by its use of caprylate or L-fucose as a sole carbon source and its hydrolysis of gelatin.[53,111] Clinically relevant strains include *S. marcescens*, *Serratia liquefaciens*, *Serratia odorifera*, *Serratia ficara*, and *Serratia plymuthica*.[19,41] For a detailed review of the properties of *S. marcescens*, the reader is referred to the review by Hejazi and Falkiner.[54]

EPIDEMIOLOGY

S. marcescens was thought to be nonpathogenic in earlier times and was used as a biologic marker of transmission in 1906. In that year, N. H. Gordon, commissioned to study the atmospheric hygiene of the British House of Commons, gargled a liquid culture of *S. marcescens* and then quoted Shakespeare to an audience of agar plates in the otherwise empty House of Commons chamber.[48,116] The organism subsequently was recovered from the plates, documenting the possibility of aerosol transmission of bacteria (Gordon reported no ill effects). The importance of *S. marcescens* as a biologic marker for hand-to-hand bacterial transmission, ascension of bacteria in the urinary tract in catheterized patients, and bacteremia after dental extraction is reviewed in detail by Yu.[116] Most remarkably, in investigations in 1950 and 1952 to judge the threat of biologic warfare to the United States, the U.S. Navy released *S. marcescens* into the Pacific, where it became aerosolized and drifted 80 miles inland.[13] Although an epidemic of *S. marcescens* infection in a San Francisco hospital coincided with this event, subsequent serotype and biotype analyses cast doubt on any relationship to the U.S. Navy experiments.[38] Rather, the early San Francisco hospital experience heralded the increased frequency of nosocomial infections that would be observed in subsequent years.[116]

In some studies, *S. marcescens* is the organism most frequently isolated from contact lens solutions and contact lens cases.[92,118] Ex vivo mouse cornea studies show that the organism adheres to injured but not to intact corneas.[92] All commercial multipurpose disinfectant solutions are active against the type strain but vary in their activity against actual clinical isolates. Polyquaternium-1–based solutions fared the worst in their activity against circulating strains.[57]

Sporadic nosocomial outbreaks of infection were reported first in the 1950s and 1960s.[72,93,114] Early outbreaks in a pediatric ward and neonatal nursery were attributed to contaminated intravenous solution and caps of bottles containing saline used to moisten umbilical cords.[72] As reviewed by Yu,[116] environmental sources before 1979 included disinfectants, water from ultrasonic nebulizers, respirators, arterial pressure monitors, and fiberoptic bronchoscopes. Environmental sources since have included suction traps,[81] intra-aortic pressure transducers,[10,112] contaminated handwashing brushes,[5] illicit intravenous drug paraphernalia,[29] contaminated urologic instruments,[36] colonized disinfectants or soaps,[37,69,74] contaminated infant parenteral nutrition fluid,[42] contaminated whole blood or blood products,[47,94] and inadequately sterilized breast milk pumps.[50] In one report, a woman elected to discontinue breastfeeding when the breast pump tubing turned bright pink and was culture positive for *S. marcescens*.[39]

Hand-to-hand transmission seems to be the primary mechanism of nosocomial spread. In one dramatic outbreak, spread of an organism with the same serotype, phage type, and antimicrobial sensitivity pattern was documented among four geographically separated teaching hospitals in the same region[99]; spread likely was due to passive carriage of *S. marcescens* on the hands of rotating personnel. By 1979, it was apparent that nosocomial increase in *S. marcescens* infection was becoming a worldwide concern.[19]

Outbreaks in neonatal units and pediatric wards have been widespread, persistent, and associated with high morbidity and mortality rates.[5,16,81,107] At the peak of one epidemic of invasive *S. marcescens* disease in a neonatal nursery, more than 90 percent of infants were colonized with the epidemic strain.[35] Increased rates of colonization have been associated with nearly 10-fold increases in rates of *S. marcescens* bacteremia and meningitis.[119] In a case-control study, neonates with *S. marcescens* bloodstream infection were at least three times more likely to have associated meningitis than were neonates whose blood cultures grew *Escherichia coli*.[14] Outbreaks of multidrug-resistant strains have been especially troublesome in surgical subspecialty wards, and an outbreak has been reported in a bone marrow transplant unit.[20,62] In the United States a multistate outbreak of *Serratia* infections was caused by contaminated prefilled saline and heparin syringes.[24]

Biotyping may be successful in characterizing isolates, which can be traced in the hospital environment.[52,106] Ribotyping or identification of a unique biochemical characteristic has proved useful for showing cross-contamination across hematology, gastroenterology, and neonatology units in a pediatric hospital.[12,43] Use of typing methods may be particularly important because drug-resistant and drug-susceptible isolates of *Serratia* organisms may co-circulate.[27] Banding differences from pulsed-field gel electrophoresis of DNA digests are restricted in number from outbreak strains; increases in banding pattern may reflect genetic drift over time.[7] Such DNA techniques have aided decisions regarding cohorting and closure of neonatal units and have been used to show cross-contamination of wards.[56,79] DNA amplification techniques offer promise for characterizing isolates in future outbreaks and defining antimicrobial susceptibility.[55,69,102]

PATHOPHYSIOLOGY

Pathologic findings of sepsis are similar to the findings of other gram-negative enteric bacilli. Postmortem examination of the lungs of patients with radiologic findings of *S. marcescens* pneumonia reveals a focal necrotizing pneumonia in most cases and hemorrhagic manifestations in some.[9]

Several properties may enhance virulence of *Serratia* organisms in human infection. The 56-kDa protease of *S. marcescens* seems to possess properties of a virulence factor. It enhances vascular permeability through activation of the Hageman factor–kallikrein–kinin pathway in vivo.[71] The protease also has the capacity to degrade host proteins important in humoral immune response, such as immunoglobulins and fibronectin,[80] and inactivates the chemotactic effect of C5a.[86] *Serratia* hemolysin indirectly may increase vascular permeability, local edema, and granulocyte accumulation.[63] Clinical strains seem to possess increased adherence properties compared with environmental isolates.[8] Compared with some enteric organisms, *Serratia* organisms adhere better to epithelial cells of the bladder, which may facilitate development of urinary tract infection.[31] Outer membrane vesicles (OMVs) are formed by *S. marcescens* in response to stress; OMVs likely play a role in virulence because it appears they function in toxin delivery.[73]

Cell-mediated immunity and humoral immunity may be important in protection from *Serratia* infection and illness. In a murine model of immunization against *S. marcescens*, only the transfer of antiserum and spleen cells from vaccinated mice increased bacterial clearance from the liver and survival after infection developed.[66] In nonphagocytic cells in vitro, *S. marcescens* can survive and even proliferate within autophage-like vacuoles by delaying or preventing fusion with lysosomes.[40]

Resistance of *S. marcescens* to aminoglycosides generally is plasmid mediated. Resistance to aminoglycosides may be conferred by one of several genes producing acetylating, phosphorylating, or adenylating enzymes.[1,2,20,58,77] Risk for acquiring infection with aminoglycoside resistance increases with exposure to these agents.[49,117] In some patients, repeated hospitalizations have shown greater importance, however, than aminoglycoside use as a risk factor for developing infection with resistant strains.[6] High levels of resistance to penicillins and cephalosporins are mediated by one or more plasmids. Cephalosporin resistance also may be derived chromosomally (see also Chapter 102).[27,45,75,89] Chromosomally mediated β-lactam resistance may be inducible in the presence of high levels of penicillin or cephalosporins, particularly when plasmid-derived β-lactamase is blocked by clavulanic acid.[21]

A group of researchers found and cloned a multidrug efflux pump of the major facilitator superfamily from *S. marcescens*.[104] Transposable plasmid elements may seem partly responsible for the rapid spread of multidrug resistance.[95,96,101] In one survey, 2.6 percent of *S. marcescens* isolates were deemed "multidrug resistant," defined as resistant to three or more classes of antimicrobial agents.[34] Plasmids conferring multidrug resistance are transferable from *S. marcescens* to *Klebsiella* spp. and may be responsible for sequential nosocomial outbreaks of different genera sharing common drug-resistance patterns.[110] A report from Spain suggested probable in vivo transmission between *E. coli* and *S. marcescens* of a plasmid containing both β-lactamase and quinolone resistance genes.[70]

CLINICAL MANIFESTATIONS

First described in a patient with bronchiectasis as a cause of "blood-tinged" sputum colored by the organism,[115] *S. marcescens* commonly is associated with urinary tract, respiratory tract, central venous catheter, and bacteremic infections.[2] Other species, including *S. liquefaciens*,

S. ficara, *S. odorifera*, and *S. plymuthica*, are less common causes of disease.[14,25,32,41,103]

Chromogenic *S. marcescens* was responsible for the historically interesting and reportedly benign "red diaper syndrome," which persisted for 7 months in the infant of a genetics professor.[113] In at least one series, the organism has been identified as one of the top five causes of neonatal sepsis[51] and now is recognized as a major pathogen of compromised newborns. Disease in neonatal intensive care units is associated commonly with high rates of underlying respiratory illness.[83] Other preexisting risk factors include necrotizing enterocolitis, surgical procedures, intravenous catheters, prolonged intubation, and cardiac disease.[14] Clinical illness shares features in common with other neonatal enteric pathogens; apnea, hypotension, and respiratory distress are seen frequently. Pneumonia with empyema has been reported.[61] Meningitis occurs as a complication in 24 percent of cases of neonatal bacteremia,[14] and antibiotic resistance may emerge during therapy for bacteremia or localized infection.[22] Significant brain injury caused by ventriculitis, brain abscesses, or porencephalic cysts is observed in most infants with meningitis.[22,67]

In older children and adults, *Serratia* spp. are isolated most frequently from the urinary tract.[2,99] Instrumentation, catheterization, and clustering of susceptible individuals are important risk factors.[6,23,58,97,100] By the 1970s, increased frequencies of serious infection, such as endocarditis, were noted in intravenous drug abusers.[29] In some series of respiratory and urinary tract infections, *S. marcescens* was observed to be associated more commonly with the complication of bacteremia than was any other enteric pathogen.[60,65] As is true of other causes of gram-negative sepsis, *Serratia* sepsis characterized by shock, pneumonia, or hemorrhage confers a substantially poorer prognosis.[15,17,98] The risk for these complications in cancer patients was observed by Saito and associates[98] to be lower, however, than their previous experience with other pathogens, such as *E. coli* and *Pseudomonas aeruginosa*. When predictive factors of mortality were sought in 385 subjects with nosocomial bacteremia, *S. marcescens* was not an independent predictor of death.[78] Other infections caused by *Serratia* include soft tissue infections, abscesses, endophthalmitis (including a case occurring after septicemia in an infant),[3,4] osteomyelitis and arthritis,[109] spinal epidural abscess, and peritonitis in dialysis patients.[28] A severe case of epiglottitis including fasciitis, myositis, and bacteremia was seen in a 58-year-old woman; prior cases were all in immune-compromised patients.[82] In one report, sternal osteomyelitis recurred 15 years after apparent successful treatment.[90]

DIAGNOSIS

The diagnosis of *Serratia* infection relies primarily on isolation of organisms from clinical material. Nonspecific laboratory tests occasionally may be misleading. *Serratia* meningitis in a neonate may be accompanied by a normal cerebrospinal fluid white blood cell count or only a modest cerebrospinal fluid pleocytosis.[22] Although *S. marcescens* is famous historically because of its chromogenic potential, most strains are nonpigmented. Hydrolysis of gelatin distinguishes *S. marcescens* from *Klebsiella* and *Enterobacter* in the clinical microbiology laboratory. The presence of ornithine decarboxylase and fermentation of sorbitol but not arabinose helps to differentiate further *S. marcescens* from other *Serratia* spp.[53] Biotyping,[52] DNA and RNA detection techniques,[69] and antimicrobial susceptibilities[106] can be used to characterize strains.

TREATMENT

Empirical decisions about antibiotic treatment of *Serratia* infection should rely on knowledge of hospital flora. Therapy should be tailored when susceptibilities are known. In newborns, meningitis and its complications should be suspected and interventions should be guided by imaging of the central nervous system. Imaging techniques may be useful in guiding needle aspiration of abscesses.[85] Recommended antibiotic therapy for neonatal meningitis is a cephalosporin and an aminoglycoside for susceptible strains. Mortality rates remain high (>45%) even with appropriate antibiotic management.[22]

In older children and adults, reported response rates for bacteremic infection have been 75 percent for patients who received appropriate antibiotics, 22 percent for patients who received inappropriate antibiotics, and 29 percent for patients who received no antibiotics.[98] Patients who continue to have positive blood culture results while receiving appropriate antibiotic therapy have a poor prognosis. In the review by Saito and associates[98] of 118 patients with *Serratia* bacteremia, patients who received only an aminoglycoside had the poorest response rate among those who received appropriate therapy; patients who received a cephalosporin, alone or in combination, fared better. *Serratia* organisms generally have proven susceptible to third-generation cephalosporins in surveys of hospitals from North America.[59] The physician needs to be wary, however, of potential resistance to cephalosporins and penicillins owing to the production of extended-spectrum β-lactamases. An extended-spectrum, metallo-β-lactamase–mediating resistance to imipenem has been described,[88] but it is uncommon. Physicians should consider strongly empirical use of a carbapenem in combination with an aminoglycoside in critically ill patients.[84] A worldwide surveillance study from 2004 to 2009 suggested that over 90 percent of *Serratia* strains were susceptible to meropenem, imipenem, and tigecycline.[11] However, outbreaks due to meropenem-resistant clones have also been described.[108]

Amikacin historically has been effective in the treatment of gentamicin-resistant strains.[30,68] In 1985, amikacin was recommended as a first-line antibiotic for treatment of pediatric nosocomial infection when *Serratia* spp. or other enteric agents with resistance potential were suspected.[105] Since the 1980s, however, outbreaks of *S. marcescens* infections caused by amikacin-resistant strains have been reported.[87] Quinolones have been used successfully for treatment of organisms resistant to other

agents,[46] but resistance to these drugs also has been identified.[64]

Cohorting and attempts to remove environmental sources of infection have been successful in ending epidemics but typically require several months.[26] Rarely, neonatal intensive care units have been closed to admissions to halt epidemics.[18,81]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 111

SALMONELLA

Theresa J. Ochoa • Javier Santisteban-Ponce

MICROBIOLOGY

Salmonellae are motile (owing to peritrichous flagella), nonencapsulated, gram-negative bacilli and facultative anaerobes of the Enterobacteriaceae family. The classification of *Salmonella* is confusing because multiple nomenclature systems are used (Table 111-1). In this chapter, we use the current designation of the Centers for Disease Control and Prevention (CDC), rather than either the complete name or the traditional clinical shorthand that referred to each of the more than 2500 serovars of *Salmonella* as though they were separate species. In hospital laboratories, *S.* ser. Choleraesuis and *S.* ser. Typhi are distinguished biochemically from other *Salmonella* spp. serogroup, based on O (somatic) antigen, also usually is determined on initial isolation, and organisms that are not *S.* ser. Typhi or *S.* ser. Choleraesuis are reported as *Salmonella* serogroup A, B, C1, D1, and so on. Common *Salmonella* spp. and their serogroups are shown in Table 111-2.

Salmonella serotype is defined by the serogroup antigens, the flagellar (H) antigens, and the virulence (Vi) antigen. H antigens can be either phase 1 (nonspecific) or phase 2 (specific). The Vi antigen, a heat-labile polysaccharide found on *S.* ser. Typhi, *S.* ser. Dublin, and *S.* ser. Paratyphi C, may block agglutination caused by antibodies to O antigen. Serotyping is an important epidemiologic tool for defining outbreaks, although it is most useful when an unusual type is associated with disease. When a common serotype is associated with an outbreak

*Human infections with organisms in serogroups E4, F, G1, G2, H, and I and the O antigens not given serogroup designation (O17 through O67) are uncommon.

(e.g., *S.* ser. Typhimurium), biochemical phenotype, antibiogram, plasmid characterization, bacteriophage typing, outer-membrane protein analysis, pulsed-field gel electrophoresis, and randomly amplified polymorphic DNA may help determine whether a single-strain, common-source outbreak is in progress.

Six subgroups of *Salmonella* have been proposed on the basis of DNA relatedness. Most serotypes, including almost all of the serotypes important in human and animal disease, belong to subgroup I. The former genus *Arizona* is reclassified as *Salmonella*.

Based in host adaptability, Salmonellae are divided in three groups. Group 1 englobes *Salmonella* highly adapted to humans and primates, group 2 identifies highly specific animal-adapted *Salmonella*, and group 3 includes those serovars not host adapted but capable of infecting both humans and a wide range of animals and consisting mainly of *Salmonella* ser. Typhimurium and *S.* ser. Enteritidis.[6] Blood agar or chocolate agar supports their growth when they are present as the sole organisms in blood, cerebrospinal fluid (CSF), or joint fluid. For specimens containing mixed flora (e.g., stool), selective media such as *Salmonella-Shigella* (SS) agar or bismuth sulfate agar must be used.

EPIDEMIOLOGY

Nontyphoidal *Salmonella*

Public Health Issues

In most of the world, the prevalence of *Salmonella* varies according to the water supply, waste disposal, food preparation practices, and climate. The incidence of nontyphoidal salmonellosis is 93.8 million gastroenteritis cases worldwide each year, causing 155,000 deaths globally.[196] In the United States the incidence of the disease has increased steadily, despite good public health interventions, while nontyphoidal *Salmonella*-related mortality declined over years.[76] During 1996 to 2009, incidence of foodborne infections in the United States has increased 44 percent,[50] and a more than sixfold increase in reported nontyphoidal *Salmonella* infection in the United States has occurred during the last 40 years, with an estimate of 168,000 physician office visits, 15,000 hospitalizations, and 400 deaths annually during 1996 to 1999.[322] This increase reflects industrial-scale food production and distribution,[49] misuse of antimicrobial agents (in humans and animals) that alter the competing gastrointestinal flora and induce multidrug-resistant strains of *Salmonella*,[317] and probably an increasing number of immunocompromised individuals in the population. Targeted interventions, including on-farm control measures, refrigeration, and education contributed to an important decrease in the incidence of *S.* ser. Enteritidis infections in the United States,[200] highlighting the importance of these efforts to further reduce the rate of *Salmonella* infection. The most recent 44 percent increase in food-related incidence of *S.* ser. Enteritidis infections is linked to eating chicken in domestically acquired episodes.[48] In some developing countries, mortality rates of nontyphoidal bacteremic *Salmonella* infections in infants remain at 20 percent or higher over years.[123]

Significance of Animal Reservoirs and Other Food Sources

In contrast to *Shigella* spp., which infect only primates, nontyphoidal *Salmonella* spp. infect a variety of animals (including poultry, livestock, and pet reptiles and rodents).[298] Salmonella has been isolated from flies, mites, and other arthropods taken from animal farm environments; it is able to multiply inside some insects and is

transmitted within insects and to birds, rodents, and livestock.[328] Those arthropods, birds, and rodents could contribute to *Salmonella* transmission to the wildlife animals.[140] Animals and animal products (including meat and dairy products), water, and infected humans can be the source of infection. *Salmonella* is the leading cause of foodborne illness in the United States, and the second most common cause of death from foodborne pathogens.[190] Spread of resistant organisms from food animals to humans has been shown.[216] *Salmonella* spp. have been isolated from 50 percent of poultry,[36] 16 percent of pork, 5 percent of beef, and 40 percent of frozen egg products in retail stores. Slicing food with contaminated tools and surfaces transfer *Salmonella* in progressively decreasing amounts per slice, resulting in higher bacterial contamination for the firstly sliced portions.[48] Undercooked eggs (e.g., in Caesar salad, egg-dipped bread, and homemade eggnog) may be contaminated by organisms on the shell surface or transovarially directly through the egg yolk. Grade A shell eggs have been implicated in more than 40 percent of more recent outbreaks.[190] Even in the absence of recognized outbreaks, undercooked eggs probably are important vehicles of infection.[139]

The impact of *Salmonella* outbreaks was shown when milk contaminated with *S.* ser. Typhimurium was distributed in Chicago, Illinois. Reports estimated that more than 150,000 people became ill, with more than 16,000 culture-confirmed cases, 2777 individuals hospitalized, and 14 fatalities.[27] Ice cream, cream cakes, and mayonnaise commonly have been incriminated as the source of infections. Fruits and vegetables are vehicles reported less frequently in outbreaks but better identified and reported in recent years as a result of molecular methods and country-wide database reporting.[28,107,186,197]

Of the 10 most frequent *Salmonella* serovars causing disease in humans, 8 are included within the 10 serovars most frequently identified in at least one of the major food-animal species.[109] Some serotypes are associated with particular reservoirs. *S.* ser. Dublin is associated with dairy cattle and is frequently found in individuals who drink raw milk.[305] *S.* ser. Choleraesuis is associated with pigs.[59] *S.* ser. Typhimurium is associated with contact with pet rodents.[298] Infection with *S.* ser. Marina is associated with contact with pet iguanas. *Salmonella* group F, *S.* ser. Typhimurium, *S.* ser. Muenchen, and *S.* ser. Java infections have been traced to pet turtles. Reptiles, including rattlesnakes, are important *S.* IIIa 18:z_4,z_{23}: *(Arizona hinshawii)* reservoirs.

Humans as a Reservoir

After infection occurs, nontyphoidal *Salmonella* spp. are excreted in feces for a median of 5 weeks. Children younger than 5 years of age may excrete the organisms for 20 weeks after having an illness, but older children and adults usually excrete *Salmonella* for less than 8 weeks. Up to 5 percent of children younger than 5 years of age have been found to excrete nontyphoidal *Salmonella* for 1 year after disease.[42] *S.* ser. Typhi may be excreted chronically, particularly in the presence of gallbladder disease and sustained by biofilms.[72] Food handlers who are excreting *Salmonella* spp. represent an important risk group. Nontyphoidal *Salmonella* infection index cases have been mapped to isolation of the same clones in 65 percent from children and adults living in the same household versus less than 2 percent of home environment samples in Africa.[164] Nontyphoidal *Salmonella* spp. may be excreted for longer periods in feces of children with primary immunodeficiency.[236]

Bacterial Characteristics Favoring Survival

Salmonella spp. survive refrigeration and sometimes heating; they may remain viable at ambient or reduced temperatures for weeks and even in low-moisture foods.[250] Salmonellae may remain viable in foods after cooking for less than 12 minutes at less than 65°C (140°F). *Salmonella* spp. are killed by heating to 54.4°C (130°F) for 1 hour or 60°C (140°F) for 15 minutes. Food industry ingredients with low water activity and high fat content provide a marked thermal resistance to *Salmonella*, making necessary use of higher heating temperatures and longer time.[250] Salmonellae survive for hours on the hands of slaughterhouse workers.[243] The organisms have been found to survive in flour for nearly 1 year. *S.* ser. Tennessee has been reported to remain viable for 2 to 8 days on glass, stainless steel, enameled surfaces, a rubber mattress, linen, and a rubber tabletop.[330] *Salmonella* small inoculates (<100 cfu/g) are able to survive 30 to 40 days in vacuum dust.[138] Nosocomial infections have been related to contaminated medical equipment (e.g., endoscopes) and diagnostic or pharmacologic preparations, particularly those of animal origin (e.g., bile salts, pancreatic extracts, pepsin, and vitamins). *Salmonella* capability to form complex surface structures called biofilms in both host and nonhost environments are an important mechanism for survival and persistence.[47,173] Biofilm formation increases resistance of *Salmonella* to disinfectants and even to antibiotics, resulting in 2000-fold resistance to ciprofloxacin in vitro.[293]

Relationship of Age to Risk for Disease

The highest incidence rates occur in children younger than 5 years of age, especially infants younger than 1 year, and in individuals older than 70 years. Among infants in the United States, the incidence of invasive salmonellosis (7.8 cases/100,000 inhabitants) is the highest within age groups.[323] Nursery outbreaks often can be traced to an infected mother,[20,176] with subsequent spread occurring through health care personnel.[280,331] The mother of the index case can be symptomatic[108,157,270] or asymptomatic,[331] recovering from recent infection,[228,284] or a chronic carrier.[277] Low-birth-weight infants seem to be at higher risk than full-term infants for acquiring *Salmonella* infection.[24,280,331] The source of infection occasionally is contaminated food, but more often it is fomites (e.g., delivery room resuscitators,[269] rectal thermometers,[153,205] suction devices,[167] water baths for heating formula,[261] soap dispensers,[213] scales,[5,25,331] tables,[331] air-conditioning filters,[331] and plumbing[210]). Outbreaks in nurseries often are extraordinarily difficult to stop. They have been reported to last months[176,233,331] to years.[108,210,301] Contamination sometimes can become so widespread that other areas

of the hospital also experience cases.[202,283] These outbreaks occur far more commonly with *Salmonella* than with other bacterial enteropathogens. Such outbreaks sometimes are caused by multiresistant *Salmonella*.[176] Multidrug-resistant *Salmonella* has been isolated from cockroaches found in a neonatal intensive care unit in Africa.[310]

Seasonality

Salmonella infection occurs throughout the year, with predominance for warm months.[177]

Inoculum Size Required to Cause Disease

The estimated inoculum size required to cause symptomatic disease in healthy adult volunteers is 10^5 to 10^{10} organisms,[34] but the number of organisms required to cause symptoms in infants and children probably is much lower. In contrast, large inocula are not required for *Shigella* infection, which occurs in adult volunteers exposed to only 10 organisms. In some outbreaks, very small inocula of *Salmonella* seem to have caused disease. Pharmacologic suppression of gastric acid secretion increase the risk for disease caused by *Salmonella*.[26] Large inocula (e.g., 10^9 organisms) may cause severe symptoms, even in healthy children.[305] The incubation period usually is 6 to 72 hours but depends on inoculum size, bacterial virulence, and host immunocompetence. Communicability parallels the duration of fecal excretion. The probability of salmonellosis occurring is increased when a member of the household is infected. Infants especially may be susceptible to acquiring *Salmonella* infection directly or indirectly from ill family members. Infants also may acquire infection via exposure to raw meat while riding in a grocery cart or while having contact with infected pets.[158] In a retrospective review of 187 infants younger than 1 year old with *Salmonella* gastroenteritis, 39 percent had at least one family contact with diarrhea, and 71 percent of the contacts had stool cultures positive for *Salmonella*.[332] *Salmonella* spp. rarely have been isolated during studies of gastroenteritis in daycare centers, suggesting that larger inocula are required to cause illness in toddlers and older children.[60,184,246]

Antibiotic Selection Pressure

Since the mid-1960s, *Salmonella* spp. have become increasingly resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX). Multiresistant strains have included *S.* ser. Typhimurium, which is the most common serotype in Europe and the United States. Antibiotic resistance usually is transferable between organisms through plasmids that carry genes encoding resistance factors. Some serotype-specific virulence plasmids form hybrid plasmids through recombination with resistance plasmids or acquire gene cassettes consisting of multiple resistance genes. Such evolutionary events provide a virulent strain with the advantage of survival in an unfavorable drug environment.[297] Patients who are infected with antibiotic-resistant strains are more likely to be hospitalized, to be very young, to be black, and to have been exposed recently to antibiotic agents.[178] Previous use of antimicrobial agents for treatment of other illnesses is a significant risk factor for acquiring multiresistant *Salmonella* infection.[193,262]

In the United States, 30.5 percent of nontyphoidal *Salmonella* isolates from blood from 1996 to 2007 were found resistant to at least one antimicrobial tested.[75]

Perhaps the most important factor is the overuse and misuse of antibiotics in animals raised for food.[67,144,145,183,292] Subtherapeutic concentrations of antibiotics used to enhance growth and prevent infection in animals promote intestinal colonization by antibiotic-resistant bacteria, including *Salmonella;* these organisms may be found in feces and may contaminate instruments and meat at the time of slaughter.[47,107] Plasmid analysis and antibiotic susceptibility patterns have linked *Salmonella* outbreaks to specific farms and slaughterhouses.[144,145,216]

Salmonella Ser. Typhi

The CDC estimates that 22 million typhoid cases occur each year in the world, with an annual incidence varying from less than 10 to more than 1000 cases/100,000 population.[276] The global mortality estimates from typhoid also have been revised downward from 600,000 to 200,000, on the basis of regional extrapolations.[74] *S.* ser. Typhi is the most common *Salmonella* isolate in many developing countries. Although the overall ratio of disease caused by *S.* ser. Typhi to disease caused by *S.* ser. Paratyphi is about 10:1, the proportion of *S. paratyphi* infections is increasing in some parts of the world,[30] sometimes paralleling *S.* ser. Typhi isolations.[73] The human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) epidemic in Africa has been associated with a concomitant increase in community-acquired bacteremia caused by nontyphoidal *Salmonella*.[29,125] In the United States, approximately 1700 total cases were reported (1 case/100,000) in 1955. In 1988, approximately 400 total cases were reported (0.018 case/100,000). Approximately 28 percent of infections occurred in individuals 19 years old or younger. Frequently, the highest incidence is stated as occurring in individuals 5 to 12 years of age. More recent population-based studies from South Asia and India suggest, however, that the incidence is highest in children younger than 5 years of age, with higher rates of complications and hospitalization.[30,287]

In the United States, individuals traveling to developing countries are a high-risk group; 62 to 81 percent of infections are related to foreign travel, especially to Mexico, India, the Philippines, Pakistan, El Salvador, and Haiti. Of these areas, the Indian subcontinent has the highest incidence of typhoid among travelers.[3,48,211,274]

Reservoir

Humans are the reservoir for *S.* ser. Typhi; infection implies direct or indirect contact with an infected person. Animal products transmit *S.* ser. Typhi if they are contaminated by infected humans during processing. The most common mode of transmission is food or water contaminated by human feces. Waterborne typhoid fever

epidemics are especially important. Congenital transmission can occur from a bacteremic mother to her fetus transplacentally[215,281] or at the time of delivery.[215]

Relevance of Inoculum Size to Disease

As with nontyphoidal *Salmonella*, more than 10^5 organisms are required to cause clinical illness in adults.[147,148]

Antibiotic Resistance

The worldwide frequency of antibiotic-resistant *S.* ser. Typhi has been increasing since the 1960s[289] but remains much lower than that of nontyphoidal *Salmonella*. Extensive protracted outbreaks have been reported throughout Asia, the Middle East, and Central and South America. These outbreaks may have been related to widespread and inappropriate use of antimicrobial agents in these areas. After sporadic outbreaks of chloramphenicol-resistant typhoid between 1970 and 1985, many strains of *S.* ser. Typhi developed plasmid-mediated, multidrug resistance to the three primary antimicrobials used (i.e., ampicillin, chloramphenicol, and TMP-SMX).[267] This pattern of simultaneous resistance of *S.* ser. Typhi to formerly recommended first-line antimicrobials (i.e., ampicillin, chloramphenicol, and TMP-SMX) is defined as multidrug-resistant typhoid fever.[344] Chromosomally acquired quinolone resistance in *S.* ser. Typhi and *S.* ser. Paratyphi has been described more frequently in some parts of Asia and the rest of the world, possibly related to the widespread and indiscriminate use of quinolones.[258,286] With the advent of quinolone resistance, third-generation cephalosporins were used for treatment, followed by occasional reports of resistance.[344]

PATHOPHYSIOLOGY

The severity and outcome of *Salmonella* infections depend on the combination of the virulence of the infecting bacterial strain, the infectious dose, the route of infection, and the genetic makeup and immunologic status of the host.

Salmonella can (1) adhere to, invade, and multiply in intestinal epithelium; (2) produce cholera toxin–like enterotoxin that increases cyclic adenosine monophosphate levels within intestinal crypt cells, causing a net efflux of electrolytes and water into the intestinal lumen; (3) be taken up by M cells overlying Peyer's patches of the distal ileum and proximal colon; (4) survive in macrophages of Peyer's patches, mesenteric lymph nodes, and the extraintestinal reticuloendothelial system; and (5) survive in the bloodstream.[106,108,116] Specific genes encode virulence factors necessary for each step in these processes and for specific disease manifestations (Table 111-3).

Pathologic findings in *S.* ser. Typhi infection include hypertrophy and hyperplasia of the intestinal and mesenteric lymphoid tissues, liver, and spleen. In contrast, *S.* ser. Typhimurium and other nontyphoidal serotypes cause diffuse colitis, mucosal edema, and crypt abscesses as the major pathologic abnormalities.[36,80]

Some virulence genes are shared by all *Salmonella* strains, whereas others are serotype-specific. Differences in invasiveness of various serotypes exist. *S.* ser. Typhi, *S.* ser. Choleraesuis, *S.* ser. Heidelberg,[152,207] and *S.* ser. Dublin[305] are more likely to enter the blood and to seed distant sites. Virulence plasmids have been identified in *S.* ser. Typhi, *S.* ser. Typhimurium, and *S.* ser. Dublin.[21] The presence of virulence plasmids seems to be more common in blood isolates of *S.* ser. Typhimurium than in fecal isolates (76% vs. 42%).[103]

Nursery outbreaks of *Salmonella* have shown dramatically the variability in severity of illness related to strain or serotype. In nursery outbreaks of *S.* ser. Oranienburg[301] and *S.* ser. Newport,[176] grossly bloody stools were found in 76 to 90 percent of infected infants, with 10 to 11 percent febrile and only 9 to 11 percent asymptomatic. Watery, green, nonbloody diarrhea has been common with *S.* ser. Typhimurium,[1] *S.* ser. Virchow,[266] and *S.* ser. Nienstedten.[283] A high frequency of asymptomatic infections has been seen during nursery outbreaks with *S.* ser. Heidelberg (38% asymptomatic),[24] *S.* ser. Virchow (42% asymptomatic),[266] and *S.* ser. Tennessee (100% asymptomatic).[331]

Which genes are required for disease in humans versus animals remains unclear. *S.* ser. Typhimurium has genes

TABLE 111-3 **Putative Pathophysiologic Basis of Selected Clinical Features of Salmonellosis**

Disease Manifestation	Mechanisms and Bacterial Genes
Bloody diarrhea	*sip* A-D–mediated invasion and interleukin-8–mediated inflammation
Watery diarrhea	*stn* enterotoxin (cholera-like toxin)
	SopB-mediated intestinal inflammation and fluid secretion
	Serotypes that induce transepithelial polymorphonuclear leukocyte migration (e.g., *S.* ser. Typhimurium) are more likely to cause diarrhea than are serotypes that do not (e.g., *S.* ser. Typhi)

that allow it to cause a nondiarrheal typhoidal illness in mice; in humans, it typically causes symptoms related primarily to intestinal involvement. An estimated more than 200 genes determine *S.* ser. Typhimurium virulence in mice. The clinical variability in host range and disease manifestations is due to the fact that *Salmonella* strains vary in their possession and expression of virulence genes.[200]

Salmonella has developed two complex virulence functions to actively interact with the host and modify host cell functions. These interactions are hallmarks of *Salmonella* pathogenesis: (1) *Salmonella* infects cells of the gastrointestinal epithelium, and are thus able to invade nonphagocytic cells; and (2) *Salmonella* may survive and replicate inside the phagocytes. Of critical importance for these interactions are the *Salmonella* pathogenicity islands (SPI), in particular SPI-1 (invasion and penetration of the gastrointestinal epithelium) and SPI-2 (systemic spread and colonization of host organs) (Fig. 111-1).[135] Both SPIs encode a molecular apparatus termed type III secretion system (TTSS). This apparatus is structurally and functionally related to the flagella assembly systems and typically contains more than 20 different protein subunits located in the inner and outer membrane and in the periplasm and cytoplasm of the bacterial cells.[135] TTSSs are capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.[65]

Genes relevant to the intestinal phase of illness are encoded primarily in SPI-1. The *invA-H* chromosomal genes are necessary for adherence to and invasion of intestinal mucosal cells[105]; most of the genes described so far seem to be involved in secretion or transport of virulence proteins.[128,316] Genes related to the *Shigella* invasion plasmid antigens *(ipaA-D)* have been described in *Salmonella* spp.[162,163]; these *Salmonella* genes *(sipA-D)* encode the proteins that interact with host cells to cause bacterial uptake and intracellular movement. The major TTSS effector proteins used to invade epithelial cells and induce inflammation in the *Salmonella typhimurium* mouse model are SipA, SopB, SopE, and SopE2.[160] Although initially characterized as an invasiveness island, SPI-1 has additional functions related to the activation of the innate immune pathway, including (1) induction of polymorphonuclear recruitment across the intestinal epithelium by the SPI-1 secreted effect SipA, (2) activation of nuclear factor-κB signaling by the concerted activity of SPI-1 translocated effectors, and (3) activation of caspase-1–mediated interleukin (IL)-1β/IL-18 activation

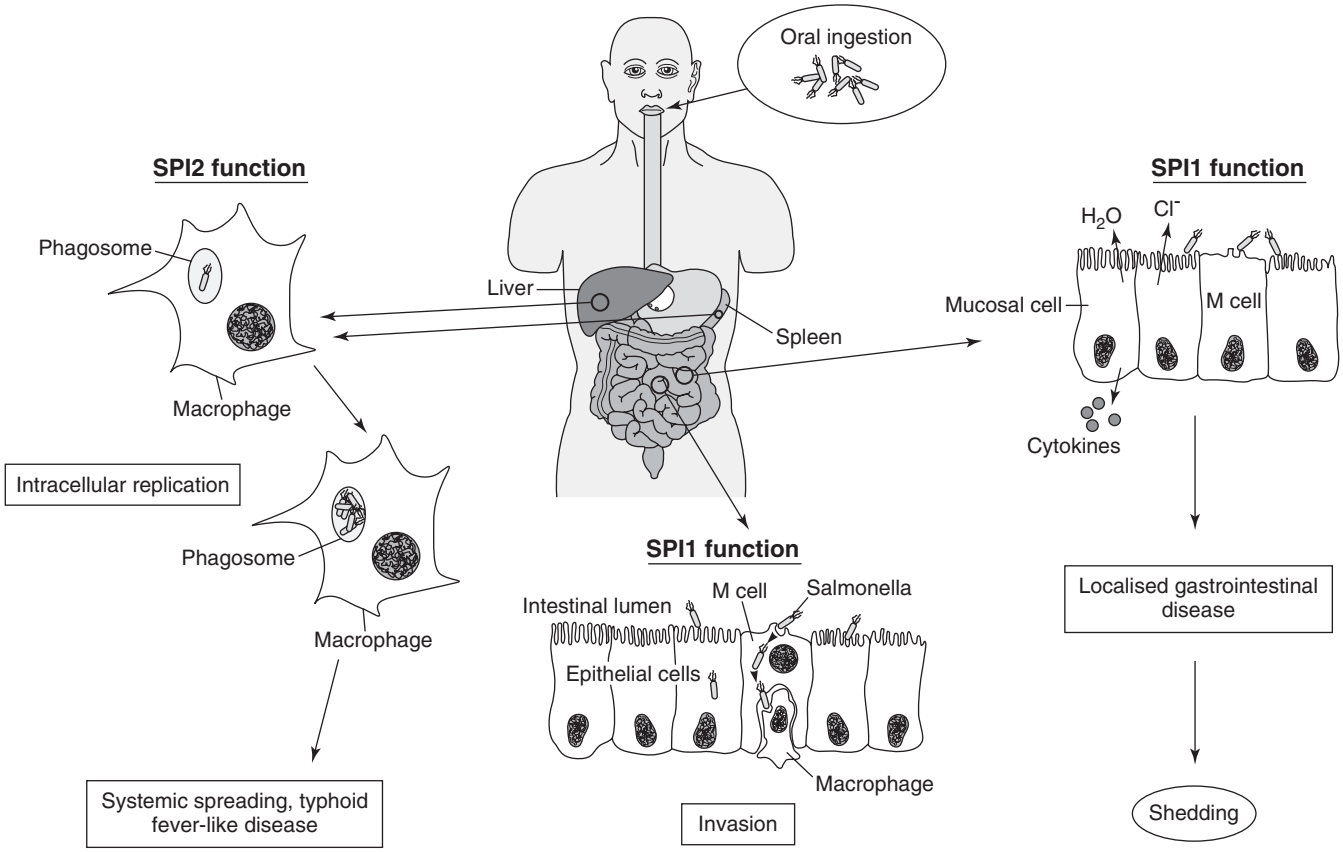

FIGURE 111-1 ■ Host-pathogen interactions during pathogenesis of *Salmonella* infection. SPI1 function is required for the initial stages of salmonellosis, that is, the entry of *Salmonella* into nonphagocytic cells by triggering invasion and the penetration of the gastrointestinal epithelium. Furthermore, SPI1 function is required for the onset of diarrheal symptoms during localized gastrointestinal infections. The function of SPI2 is required for later stages of the infection, that is, systemic spread and the colonization of host organs. The role of SPI2 for survival and replication in host phagocytes appears to be essential for this phase of pathogenesis. (From Hansen-Wester I, Hensel M. *Salmonella* pathogenicity islands encoding type III secretion systems. *Microbes Infect* 2001;**3**:549–59)

and proinflammatory cell death by the SPI-1 translocator effector SipB.[65]

The role of host cells in the invasion process is complex. After *S.* ser. Typhimurium comes in contact with epithelial cells, activation of epidermal growth factor receptor occurs, which activates a kinase that turns on phospholipase A_2 so that arachidonic acid is generated. Arachidonic acid is converted to leukotriene D_4, which opens calcium channels and causes membrane ruffling, cytoskeletal changes, and uptake of bacteria.[105] Nonphagocytic cells, including epithelial cells, are adapted poorly for killing of internalized bacteria. Not only do *Salmonella* spp. survive in vacuoles within epithelial cells but they also can replicate actively.[106] *S.* ser. Typhi survives better in human than in mouse macrophages, whereas *S.* ser. Typhimurium survives better in mouse macrophages.[41,81,282] *Salmonella* is capable of infecting a wide variety of cells, including dendritic cells, macrophages, hepatocytes, neutrophils, colonocytes, and other epithelial cells. In vitro, within minutes of contact with cells, *Salmonella* organisms are internalized and take up residence in a unique membrane-bound compartment distinct from a phagosome or lysosome, the *Salmonella*-containing vacuole.[124] Live neutrophils recruited during acute *Salmonella* colitis engulf pathogens in the gut lumen and may thus actively engage in shaping the environment of pathogens and commensals in the inflamed gut.[187]

SPI-2 is essential for intracellular parasitism and systemic virulence in murine typhoid and for evasion of phagocyte oxidase machinery of the host.[320] Intracellular replication occurs in a specialized membrane compartment, the *Salmonella*-containing vacuole, and depends on translocation of approximately 30 effector proteins via the SPI-2 TTSS into the host endomembrane system and cytoplasm.[104] SPI-2 has additional roles in inflammatory disease, such as induction of cyclooxygenase and modulation of host cytokine expression and signaling. In addition, SPI-2 function affects antimicrobial defense mechanisms of the host, intracellular transport processes, integrity and function of the cytoskeleton, and host cell death.[174] SPI-2 is crucial for early and complete induction of enterocolitis and systemic disease.[65]

Several pathogen-associated molecular patterns of pathophysiologic importance are presented by *Salmonella* during infection, principally lipopolysaccharides and flagellin. The activation of Toll-like receptor (TLR)4 in response to *Salmonella* lipopolysaccharides is essential for inducing host responses.[319] *Salmonella* flagellin is a potent inducer of host inflammation in polarized epithelial monolayers when delivered to the basolateral surface of the epithelium. When delivered there, *Salmonella* flagellin induces IL-8 secretion by stimulating basolateral TLR5.[345] Flagellin stimulation of innate immune responses is crucial for intestinal inflammation but not for murine typhoid.[65]

The development of diarrhea depends on host and pathogen factors. An influx of polymorphonuclear leukocytes into the mucosa must occur for diarrhea to develop.[329] Neutropenic animals fail to develop fluid secretion when they are infected with *Salmonella*[329]; infiltration of leukocytes is thought to trigger production of prostaglandin because fluid secretion can be blocked by indomethacin.[117] A cholera toxin–like enterotoxin is made by approximately two thirds of *Salmonella* strains, including *S.* ser. Typhimurium and *S.* ser. Typhi.[155]

For most nontyphoidal *Salmonella* strains, infection does not extend beyond the lamina propria and the local lymphatics. In contrast, *S.* ser. Typhi, *S.* ser. Dublin, and *S.* ser. Choleraesuis rapidly invade the bloodstream, with little intestinal involvement. Some virulence genes confer a survival advantage to the organisms if they get into the extraintestinal milieu. Vi capsular antigen present in *S.* ser. Typhi, *S.* ser. Dublin, and *S.* ser. Paratyphi C interferes with C3 binding. Mutations in lipopolysaccharide genes decrease invasiveness of *S.* ser. Typhi and *S.* ser. Choleraesuis, but not of *S.* ser. Typhimurium.[106,222] *S.* ser. Dublin, *S.* ser. Typhimurium, and *S.* ser. Enteritidis have virulence genes that confer resistance to complement by preventing the formation and insertion of the C5b-9 membrane attack complex.

The mechanisms governing homeostasis and immune defense are of great importance for *Salmonella* infection. *Salmonella* uses multiple strategies to evade and modulate host innate and adaptive immune responses, to persist in the presence of a robust immune response.[219] Chronically infected hosts are often asymptomatic and transmit disease to naïve hosts via fecal shedding of bacteria, thereby serving as a critical reservoir for disease. The ability of *Salmonella* to persist depends on a balance between immune responses that lead to the clearance of the pathogen and avoidance of damage to host tissues.[271] In addition, the intestinal microbiota plays a critical role in controlling *Salmonella* infection, disease, and transmissibility.[219] However, the molecular nature of the homeostatic interactions, the pathogen's ability to overcome colonization resistance, and the triggering of native and adaptive mucosal immune responses are still poorly understood.[160,161]

Host Factors

Multiple host defense strategies have evolved to deal with the bacteria virulence factors; host susceptibility often can be related directly to defects in these defense mechanisms (Table 111–4). The host tries to kill ingested organisms in the stomach, to inhibit their growth in the gut, to limit their spread beyond the intestine, and to clear them by immune mechanisms. At a pH of 2.0, most *Salmonella* spp. are killed rapidly.[115] When gastric pH is increased by oral administration of antacid, susceptibility increases.[114,147,148,262] A *Salmonella* inoculum ingested in water passes through the stomach more rapidly than when the same inoculum is ingested in food. Rapid transit through the small bowel decreases the contact time of organisms with the mucosa. Patients with decreased intestinal motility caused by medication or anatomic factors have increased severity and complications and may have a prolonged carrier state. Prior antimicrobial exposure increases the risk for incurring infection with antimicrobial-susceptible and antimicrobial-resistant strains of *Salmonella*.[242] The normal flora may compete for substrates, lower the local pH by production of short-chain fatty acids, and produce antibacterial substances such as colicins. Some patients with gastroenteritis have

TABLE 111-4 **Susceptibility to Salmonella Species Infection**

Patient Group at Risk	Mechanism
Newborn	Achlorhydria, rapid gastric emptying
	Poorly developed cell-mediated immunity
	Complement deficiency
	Immunoglobulin deficiency in premature infants
Sickle-cell anemia	Reticuloendothelial system overload owing to hemolysis
	Functional asplenia
	Tissue infarcts
	Defective opsonization
Neutropenia (congenital or acquired)	Polymorphonuclear neutrophils needed for killing
Chronic granulomatous disease	Defective killing by polymorphonuclear neutrophils
Defects of immune system IL-12/interferon-γ axis	Defective signaling resulting in failure to activate macrophages and recurrent/persistent infection by nontyphoid *Salmonella*
Acquired immunodeficiency syndrome	Low CD4
	Effects of malnutrition on cell-mediated immunity
	Survival of organisms in macrophages (owing to *Salmonella* genes *PhoP/PhoQ, spvA-D, R*)
Organ transplantation, immunosuppression	Defective cell-mediated immunity
Gastrectomy	Loss of stomach acid barrier
Malaria	Reticuloendothelial overload during hemolysis
	Abnormal complement levels
	Abnormal macrophage function
Bartonellosis (verruga peruana)	Reticuloendothelial overload during hemolysis
Schistosomiasis	*Salmonella* sequestered in schistosomes protected from host defenses and antibiotics

progression or exacerbation of symptoms when antibiotics are given.[265]

Children with compromised immune systems are at increased risk for serious focal infections. *Salmonella* organisms are able to survive in macrophages but not in polymorphonuclear leukocytes. Patients with neutropenia (e.g., congenital or related to chemotherapy) or neutrophil dysfunction (e.g., chronic granulomatous disease) are at high risk for development of disseminated infection. Patients who have been bacteremic with a nontyphoidal *Salmonella* strain are at increased risk for having a relapse if leukopenia is present.[112]

An increased risk for acquiring disease exists in settings in which reticuloendothelial function or cell-mediated immunity is impaired[226,291] or immature.[225] Hemolytic anemias are thought to cause reticuloendothelial overload. Children with sickle-cell anemia are at risk for developing bacteremia and osteomyelitis.[4,199,299,338] Children with sickle-cell and S-Thal also sometimes develop osteomyelitis.[66] Patients with sickle-cell anemia have complement defects and defects in opsonization of *S.* ser. Typhimurium.[134] Newborns also have complement deficiencies that may explain the high frequency of *Salmonella* infection in newborns and the susceptibility of newborns to bacteremic complications seldom seen in normal hosts.

Malaria predisposes to salmonellosis by multiple mechanisms.[192] Schistosomiasis predisposes to development of *Salmonella* infections and prolonged bacteremia[262]; reticuloendothelial cell killing of *Salmonella* is impaired, and *Salmonella* colonizes the schistosomes. Pili on *Salmonella* adhere to the surface of *Schistosoma mansoni* and *Schistosoma haematobium*.[188] In Gabonese children with bacteremic nontyphoidal *Salmonella* infection, rectal biopsy specimens showed the eggs of *Schistosoma intercalatum* in 90 percent of cases.[113]

Immune Response

The innate immune system provides the first line of defense against invading microorganisms by inducing a variety of inflammatory and antimicrobial responses. A distinctive feature of *Salmonella* is that it has not only adapted to survive in a strong inflammatory environment, but it also uses this adaptation as a strategy to gain a growth advantage over the intestinal microbiota. The gastric innate immune response to *Salmonella* is complex. First, following the invasion of the mucosa, the presence of *Salmonella* is detected by pattern recognition receptors. Extracellular *Salmonella* are detected by TLRs inducing a transcriptional response leading to the expression of proinflammatory cytokines such as IL-23. Intracellular *Salmonella* activate NOD-like receptors that can induce IL-23 expression, as well as the assembly of NLRC4/NLRP3 inflammasomes that activate caspase-1, promoting the secretion of mature IL-1b and IL-18. SPI-1 mediated activation of caspase-1 in epithelial cells might contribute to IL-18 secretion. Furthermore, IL-18 and IL-23 amplify the inflammatory response by paracrine signaling. IL-18 induces the release of IFNc from T cells, and IL-23 induces the release of IL-22 and IL-17. These cytokines induce the increased production of mucins and antimicrobial peptides, and promote the release of CXC chemokines, leading to an influx of neutrophils into the mucosa.[39]

Cell-mediated immunity generally is thought to be more important than humoral immunity in clearance of *Salmonella* organisms. T-cell activation of macrophages is necessary to kill intracellular *Salmonella* organisms.[195] Oral immunization with an attenuated typhoid vaccine primes lymphocytes to produce cytokines typical of a T_H1 response (high interferon [IFN]-γ/low IL-4) to the flagellar antigen.[302] Healthy individuals vaccinated with either oral or parenteral typhoid vaccines develop

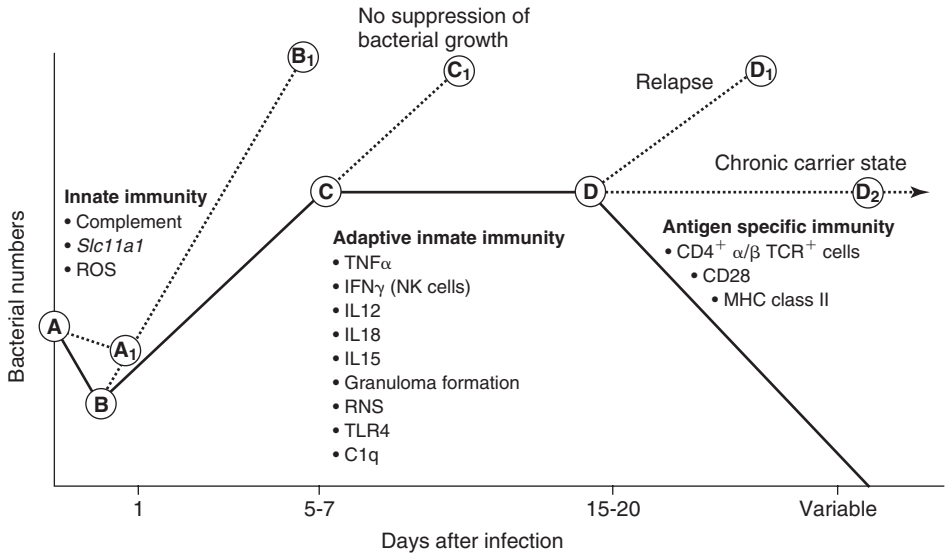

FIGURE 111-2 ■ Immunologic mechanisms that control the progression of a sublethal *S. enterica* infection in the mouse model. The *solid line* in the graph shows the course of a sublethal infection in wild-type immunocompetent mice. The *dotted lines* show the course of the infection when immunologic mechanisms required at points *A→D* are absent. Lack of complement and/or reactive oxygen species (*ROS*) affects the early blood clearance and killing of the bacteria with a shift of the growth curve from *A→B* to *A→A1*. The *Slc11a1* gene and ROS influence the net growth rate and their absence determines a shift of the curve from *B→C* to *B→B1*. Point *C* coincides with the onset of the adaptive innate immunity response. The lack of any of the immunologic factors that form part of adaptive innate immunity determines failure to suppress bacterial growth in the tissues *(C→D)* and the unrestrained progression of the infection process *(C→C1)*. Point *D* coincides with the intervention of antigen-specific immunity that is required to clear the infection and prevent relapse *(D→D1)* of the establishment of a chronic carrier state *(D→D2)*. (From Mastroeni P, Maskell D, editors. *Salmonella infections*. Cambridge, Mass: Cambridge University Press; 2006, p. 209).

antibody-dependent cellular cytotoxicity mediated by IgA, IgG, or both.[77] Studies of serum and secretory antibodies to O and H antigens have not shown protection, however; relapses of typhoid fever have occurred despite high antibody titers. Immunity may be short-lived. In a study of 14 individuals (17 to 28 years old) with acute typhoid fever, cell-mediated immunity persisted for 16 weeks; intestinal secretory IgA persisted for 48 weeks; and IgG, IgM, and anti-O and anti-H agglutinins persisted for 2 years, 16 weeks, 16 weeks, and 36 weeks, respectively.[279]

Cytokines play a crucial role in initiating and regulating the innate and adaptive immune response against *Salmonella*. These bacteria can trigger synthesis of cytokines and chemokines in epithelial cells, macrophages, and dendritic cells. The consequences of cytokine activation vary. Although IFN-γ, IL-12, tumor necrosis factor-α, IL-18, transforming growth factor-β, and CCL2 have protective functions during *Salmonella* infection, IL-4 and IL-10 interfere with host defenses.[94] The main immunologic mechanisms that control the course of *Salmonella* infection in mice are described in Figure 111-2.[203]

Impaired cell-mediated immunity probably explains the high frequency of bacteremia with nontyphoidal *Salmonella* strains in children with HIV infection[273] and with malnutrition.[288] Defective cell-mediated immunity can be congenital or acquired (from tumors,[132] collagen vascular disease, organ transplantation,[96] chemotherapy, glucocorticosteroids).[256] Inherited deficiency in the IL-12/IL-23/IFN-γ pathway results in susceptibility to recurrent *Salmonella* and *Mycobacterium* infections.[86] Defects have been described in which patients have mutations in IL-12, IL-12 receptor, IL-23, IL-23 receptor, IFN-γ receptor, and signal transducer and activator of transcription (STAT). Complete and partial deficiency syndromes have been described.[10,15,159] Isolated persistent or recurrent nontyphoidal *Salmonella* infection without history of infectious episodes by other microorganisms has been reported in 15 percent of children with deficiency of β-1 receptor for IL-12.[81]

Humoral immunity is less important. Preterm neonates who are infected with *S.* ser. Typhimurium may have a lower risk for developing complications (e.g., intestinal perforation, meningitis, endophthalmitis, sepsis, and pyelitis), however, if they are given intravenous immunoglobulin plus cefoperazone than if given cefoperazone alone (16% vs. 82%); the mortality rate also is decreased (12% vs. 41%).[122]

CLINICAL MANIFESTATIONS

Salmonella spp. may cause acute or chronic asymptomatic infection. Symptomatic infections include acute gastroenteritis, bacteremia with or without local suppuration, and enteric fever.

Acute Asymptomatic Infection

Asymptomatic infections usually are identified by stool cultures obtained during prospective research studies or

epidemiologic investigations. A study of Mexican infants showed that 74 percent of nontyphoidal *Salmonella* infections were asymptomatic.[71]

Acute Gastroenteritis

The most common clinical illness caused by *Salmonella* infection is gastroenteritis. Nausea, vomiting, and crampy abdominal pain begin 6 to 72 hours (median, 24 hours) after ingestion of contaminated food or water. The abdominal pain may be severe enough to suggest appendicitis. Diarrhea usually is moderate in volume and, depending on the serotype, may contain blood. Dysentery is a more common presentation in children from developed countries in contrast to those from developing regions.[245] Headaches, malaise, myalgias, and fevers are common. These symptoms usually resolve in approximately 1 week without antibiotic therapy; symptoms may persist in very young patients and patients with underlying diseases. In neonates, loose, green, mucous stools or, less often, bloody diarrhea is seen; fever is common with *Salmonella* gastroenteritis during the first months of life.[152] Reactive arthritis develops rarely in children after having *Salmonella* gastroenteritis.

Bacteremia with or Without Metastatic Focal Infection

Some *Salmonella* serotypes (e.g., *S.* ser. Typhi; *S.* ser. Choleraesuis; *S.* ser. Paratyphi A, B, and C; *S.* ser. Heidelberg; *S.* ser. Typhimurium; *S.* ser. Enteritidis; *S.* ser. Saint-Paul; *S.* ser. Newport; *S.* ser. Panama; and *S.* ser. Dublin) have a propensity to invade the bloodstream; others (e.g., *S.* ser. Tennessee and *S.* ser. Weltevreden)[334] rarely seem to cause bacteremia. *Salmonella* has been found as one cause of occult bacteremia in infants and children,[8,170] and when not treated with appropriate parenteral antibiotics, 45 to 68 percent of infected children developed persistent *Salmonella* bacteremia.[175] *Salmonella* is also found within cases of clinically suspected community-acquired invasive bacterial disease in children from tropical regions.[13] Fever, chills, diaphoresis, myalgias, anorexia, and weight loss may last for days or weeks. Stool cultures may be negative. A child sometimes can have afebrile diarrhea and yet be bacteremic for several days.[165] Warm climate, previous gastrointestinal disease, and recent exposure to antibiotics are some reported risk factors for bacteremia in children.[127] Severe malnutrition, HIV infection, prolonged illness, and recent hospital admission are risk factors for nontyphoidal *Salmonella* bacteremia in developing countries.[37] The true frequency of bacteremia is unclear. Depending on the patient's age, geographic location, and nature of the study (prospective vs. retrospective), 2 to 45 percent of infections are bacteremic.* Bacteremia probably occurs more commonly in newborns (in some studies 30% to 50%) than in older children,[152] although this is debatable.[207] The true risk for bacteremia developing in the first year of life is likely to be 2 to 6 percent.[78,311]

TABLE 111-5 **Focal Infections in Nontyphoidal Salmonellosis**

Organ or System	Focal Infection
Brain	Meningitis
	Brain abscess and empyema
Osteoarticular	Arthritis
	Osteomyelitis
	Pyomyositis and psoas abscess
	Prosthetic osteoarthritis
	Subcutaneous abscess
Cardiovascular	Endocarditis
	Pericarditis
	Mycotic aneurysm
	Myocardial abscess
	Septic thrombophlebitis
Respiratory tract	Retropharyngeal and pharyngeal abscess
	Pneumonia and empyema
Other	Urinary tract infection
	Epididymitis and orchitis
	Reiter syndrome
	Endophthalmitis
	Suppurative lymphadenitis

Hemolytic anemia, especially sickle-cell anemia, is associated with a high risk for development of *Salmonella* bacteremia.[221] Persistent or recurrent bacteremia occurs in patients with AIDS, schistosomiasis, and intravascular focal infection.[221] Immunocompromised adults who become bacteremic with *Salmonella* are more likely to do so without having had preceding gastroenteritis and to have a high mortality rate.[136] Children more typically are relatively immunocompetent; most often, they develop bacteremia associated with diarrhea and have a much better prognosis.[179,207] In a large study in African children, nontyphoidal *Salmonella* spp. were the second most common cause of community-acquired bacteremia in all children and in HIV-positive patients.[29] The risk for development of focal infections during bacteremia is higher (36%) in children with underlying conditions than in previously healthy children (2.5%).[342]

Focal suppurative infections may occur almost anywhere (Table 111-5); the most common sites are bones (particularly in sickle-cell anemia)[214,260] and the central nervous system.* Meningitis has a high morbidity, with acute hydrocephalus, seizures, ventriculitis, abscesses, subdural empyema, and cerebral infarction.[339] Long-term neurologic sequelae include developmental delay, which could be severe, motor disabilities (i.e., cranial nerve palsy, hemiparesis, cuadriparesis), chronic hydrocephalus, epilepsy, visual and auditory impairment, and athetosis.[67,235,339] Neurologic sequelae are particularly common in infants with delayed presentation, prolonged fever (>10 days) or seizures during hospitalization, and marked alteration of consciousness on admission.[150,235,339] Mortality rates from meningitis were 40 to 60 percent before

*References 40, 90, 169, 189, 264, 342.

the introduction of third-generation cephalosporins, fluoroquinolones, and carbapenems. With the use of these antibiotics the mortality rate has decreased to almost 10 percent but still with a high rate of sequelae.[235,339] Relapses even after prolonged therapy occur commonly (reflecting the intracellular localization of *Salmonella* and the difficulty of achieving adequate intracellular levels of antibiotics). Of nontyphoidal *Salmonella* meningitis, 50 to 75 percent occur in the first 4 months of life.[66,235] The serotypes causing meningitis, including *S.* ser. Typhimurium, *S.* ser. Heidelberg, *S.* ser. Enteritidis, *S.* ser. Saint-Paul, *S.* ser. Havana, *S.* ser. Oranienburg, *S.* ser. Newport, and *S.* ser. Panama,[66,332] are commonly associated with bacteremia. In infants, complications include pneumonia,[24] osteomyelitis,[84,172,338] septic arthritis,[24,280] pericarditis,[133,206] pyelitis,[301] peritonitis,[1] otitis media,[1] mastitis,[224] cholecystitis,[131] endophthalmitis,[70] cutaneous abscesses,[253] and infected cephalohematoma.[84] In adults and occasionally in older children, femoral and distal aorta (mycotic aneurysms),[66] heart valves,[66] scrotum,[314] testicles,[66] prostate,[278] ovaries,[66] and fallopian tubes[278] also may be infected.

Hemolytic-uremic syndrome associated with *S.* ser. Typhimurium[91,204] and *S.* ser. Typhi[22] has been reported. Because the cytotoxins produced by various *Salmonella* strains are distinct immunologically from Shiga toxin produced by *Shigella dysenteriae* 1 and the Shiga toxins produced by enterohemorrhagic *Escherichia coli*,[16] the association of hemolytic-uremic syndrome with salmonellosis may represent undiagnosed dual infection with toxin-producing organisms.

Enteric Fever

Enteric fever usually is caused by *S.* ser. Typhi and, less often, other invasive *Salmonella*, including *S.* ser. Paratyphi and *S.* ser. Choleraesuis. The onset of symptoms in enteric fever is usually insidious.[147,148] After an incubation period of 10 to 14 days (range, 6 to 21 days), which generally is related to the inoculum size, fever, malaise, anorexia, and abdominal pain develop over 2 to 3 days. The incubation period tends to be shorter with paratyphoid fever. The temperature rises in small increments, usually reaching 40° to 40.5°C (104° to 104.9°F) by the end of the first week of illness. The temperature does not return to normal but rather rises to higher peaks each afternoon, with higher nadirs occurring each subsequent morning during the first week. Eventually, the fever is unremitting; spikes in temperature occur without return to normal. In younger children, onset of fever is more abrupt on onset and then could turn intermittent or remain sustained.[97]

Constipation occurs in older children and tends to appear later on in the course,[168] whereas diarrhea is more frequent in younger children and occurs in almost one third of patients.[208,308] When diarrhea develops, it usually does so after the patient has been febrile for several days[168] and tends to be more frequent in children from nonendemic settings, where it can even lead to dehydration.[295] It is small in volume and of loose consistency, resembling a greenish pea soup; it contains erythrocytes but usually is not grossly bloody.[92,208,294] Fecal leukocytes are present in nearly all patients with diarrhea.[92] Diarrhea occurs more commonly with paratyphoid than with typhoid fever.[308] Vomiting is mild and not sustained.

A dull, continuous frontal headache begins during the first 2 days of fever and is easier to explore in adolescents.[168] Children commonly complain of headache and often are drowsy, irritable, or delirious.[83]

A relative bradycardia for the degree of fever can be found over the first week, but it is not a constant or specific finding.[79,303] Patients have a toxic facies; coated tongue; a musty, "damp hay–like" odor; and a tender, doughy abdomen with slight guarding. Occasionally, a child may have a low-level cough. The skin is dry with little sweating. Meningismus may occur early in the illness.

During the second week, rose-colored spots measuring 2 to 4 mm may appear on the abdomen or chest and rarely on surrounding locations. They are blanching, erythematous, slightly raised lesions that last approximately 3 days. Rose spots occur in a few patients and are difficult to recognize in dark-skinned individuals. Infrequently, new crops of rose spots continue for 1 to 2 weeks.

A soft, tender spleen becomes palpable by the second week of illness. Respiratory symptoms may progress, and epistaxis occasionally may occur. If left untreated, enteric fever has a prolonged course, with continuous high temperature of 39.5° to 40.5°C (103.1° to 104.9°F) for up to 4 weeks, followed by a gradual return to normal beginning during the third or fourth week. A rapid decrease in temperature late in illness suggests intestinal hemorrhage or perforation[33]; such a decline in temperature typically is followed by an increase a few hours later as peritonitis develops. Intestinal hemorrhage and intestinal perforation[33,44,118] may occur in the second to fourth week in 3 percent of patients with typhoid fever.[44]

Complications occur in 10 to 15 percent of patients; most of these develop during the second or third week of illness. Many complications, of which gastrointestinal bleeding, intestinal perforation, and typhoid encephalopathy are the most important, have been described (Table 111-6).[181,234,239,255,333] Gastrointestinal bleeding is the most common, occurring in 10 percent of patients.[239] It results from erosion of a necrotic Peyer's patch through the wall of an enteric vessel. Suppurative lymphadenitis,[223] tonsillitis,[156,278] endocarditis,[88] and pancreatitis[14,201,340] rarely occur. Patients who have thalassemia or glucose-6-phosphate dehydrogenase deficiency may have hemolysis during typhoid fever.[308]

The relapse rate is 5 to 10 percent, even when appropriate therapy has been given.[7] Relapses typically occur 2 to 3 weeks after the resolution of fever and are milder than the initial illness. The *Salmonella* isolate from a patient in relapse usually has the same antibiotic susceptibility pattern as the isolate obtained from the patient during the original episode. Reinfection also may occur and can be distinguished from relapse by molecular typing.[325]

In some geographic areas, such as Indonesia, where an exceptionally virulent *S.* ser. Typhi is endemic, toxemia, delirium, obtundation, coma, and shock sometimes occur.[147,148,181] Some serotypes in Indonesia (e.g., H1-j) seem to be less virulent than others, suggesting that

properties of the flagellar antigen may be important to virulence.[129]

Typhoid fever varies in its clinical course. Variations on the classic theme include a completely afebrile course occurring in debilitated patients, a high spiking fever from the first day (particularly in children), a focal presentation (e.g., pneumonia and nephritis), and a severe course during relapses. Infants are said to be at higher risk for development of massive hepatomegaly, thrombocytopenia, and other complications.[254] The mortality rate is high in the neonatal period.[257] Children younger than 5 years of age may have a nonspecific illness that is not recognized clinically as typhoid[287]; infants and toddlers often have a febrile illness misinterpreted as a "viral syndrome." In children younger than 2 years, the fever may last for only 1 to 5 days, despite the presence of *S.* ser. Typhi or *S.* ser. Paratyphi in the blood; low-grade fever (temperature of 38.3° to 38.8°C [100.9° to 101.8°F]) and cough may be the only findings in such children.[102] The case-fatality rates are highest among children younger than 1 year and among elderly patients. The most important contributor to a poor outcome is probably a delay in instituting effective antibiotic treatment.[239]

Enteric fever from infection with multidrug resistant *Salmonella* ser. Typhi (MDRST) in children is more frequently associated with the presence of fever, toxic appearance, hepatomegaly, splenomegaly, and abdominal tenderness and distention on admission in contrast non-MDRST.[344]

Typhoid and nontyphoidal *Salmonella* infections during pregnancy increase the risk for spontaneous abortion.[213,296] Spontaneous abortion or premature labor usually can be prevented by early treatment.[285] Transmission of *S.* ser. Typhi rarely occurs in utero.[55] Typically, premature delivery occurs during the second to fourth week of untreated maternal typhoid fever.[126] In the preantibiotic era, 40 percent of women with typhoid delivered prematurely; the remainder carried to term, although only 17 percent of infants survived.[82] If infection occurs late in gestation and is treated appropriately, the infant may survive.

Asymptomatic Chronic Carrier State

Chronic carriers excrete *Salmonella* organisms in stools for longer than 1 year after having gastroenteritis-enterocolitis or enteric fever. Approximately 1 to 4 percent of patients who recover from enteric fever caused by *S.* ser. Typhi chronically excrete the organism[212]; fewer than 1 percent of patients with nontyphoidal *Salmonella* excrete for a prolonged period.[42,51] Twenty-five percent of prolonged carriers have no history of typhoid.[239] Nontyphoidal infection is associated with excretion for a mean of 5 weeks, although children younger than 5 years of age,[42] female patients, elderly patients, and patients with biliary tract disease are more likely to become carriers. The biliary tract is infected in almost all chronic carriers of *S.* ser. Typhi. As many as 10^6 organisms per 1 g of feces may be excreted.[212]

Chronic excretion in such patients serve as the source of infection to their contacts. Chronic carriers represent an epidemiologically important reservoir of *S.* ser. Typhi; they often are the source of outbreaks of typhoid fever. In the United States, although typhoid fever generally is imported, 30 percent of infections result from exposure to previously diagnosed or newly diagnosed chronic carriers.[275]

Patients who have a history of *Salmonella haematobium* or tuberculous infections of the urinary tract may develop chronic urinary carriage after a bout of typhoid fever.[99,263]

DIAGNOSIS

The symptoms in *Salmonella* gastroenteritis overlap sufficiently with symptoms seen in other diarrheal illnesses that laboratory studies generally are required to prove the diagnosis. Proctoscopy is rarely done; typical findings include mucosal edema, hyperemia, friability, and hemorrhages.[80] The fecal leukocyte examination is positive for polymorphonuclear leukocytes in 36 to 82 percent of nontyphoidal cases,[137] but this finding is nonspecific. Stool culture is preferable to swab culture, particularly for evaluation of long-term carriers. Overnight enrichment in selenite broth increases the yield from stool

cultures. The optimal agar for isolation of the organism (SS, Hektoen enteric, MacConkey, xylose-lysine-deoxycholate, xylose-lysine-Tergitol 4, brilliant green, or modified semisolid Rappaport-Vassiliadis medium) is debated. Modified semisolid Rappaport-Vassiliadis medium has a high yield but cannot be used for isolating *S.* ser. Typhi or nonmotile strains and has lower specificity than SS agar.[272] Increasing the volume of stool sample improves the yield of *Salmonella* in cultures.[324]

Salmonella organisms usually can be isolated readily from blood by use of conventional media if the patient is bacteremic. In patients with extraintestinal focal nontyphoidal infection, specimens from the affected areas may have positive Gram stains and grow the organism.

Enteric fever should be suspected on the basis of the setting and clinical course. Laboratory abnormalities are common but nonspecific findings. Normocytic, normochromic anemia and leukopenia or neutropenia, perhaps caused by hemophagocytosis in the bone marrow, often are present.[198] Clotting abnormalities consistent with disseminated intravascular coagulation (e.g., thrombocytopenia, hypofibrinogenemia) may occur[43] but usually are transient and not associated with clinically significant bleeding. In enteric fever, electrolyte values usually are normal, but increases in alkaline phosphatase, serum lactate dehydrogenase, serum aspartate aminotransferase, and serum cholesterol occur frequently. Transient proteinuria sometimes occurs during the first week of enteric fever.

Cultures from multiple sites should be submitted for suspected enteric fever; culture of bone marrow has the highest yield,[141,143,315] particularly if the patient has had antibiotic pretreatment. During the first week of typhoid fever, approximately 90 percent of patients have positive blood and bone marrow cultures, but negative stool and urine cultures. During subsequent weeks, the yield of blood and bone marrow cultures decreases as the yield of stool and urine cultures increases. Culture of duodenal fluid obtained by string capsules can be as sensitive as culture of bone marrow aspirates.[19,143,315] Over the third week of enteric fever, bone marrow culture could remain positive despite negative blood cultures.[327] Ratio of nonviable to viable *Salmonella* bacteria in blood ranges from 1000:1 to 47,000:1.[23] The overall frequencies of positive cultures during the course of typhoid are found in blood (40% to 54%), urine (7% to 10%), stool (approximately 35%), bone marrow (80% to 90%), rose spots (~65%), and duodenal string test culture (58% to 85%).[119,143]

Blood volume is the most important factor for *Salmonella* isolation in blood cultures, and it is recommended 10 to 15 mL be drawn per sample from infants, as in adults.[335] Because bacterial counts in blood are higher in children[324] and the volume of samples are sensible both for personnel and caregivers, recommended blood volume for toddlers and infants is 2 to 4 mL.[335] The Widal test measures antibodies against the O and H antigens of *S.* ser. Typhi. Although many patients with enteric fever may have a fourfold increase in the titer of paired sera during the second week of illness, many false-negative and false-positive test results occur. Widal test titers could rise before clinical onset of disease, preventing the expected fourfold rise in titers of paired sera.[241] False-positive results of the Widal test can be caused by infection with other Enterobacteriaceae, malaria, dengue, nontyphoidal *Salmonella*, and other diseases and previous exposure to *Salmonella* antigens (including typhoid vaccines). Variability and poor standardization of commercial test antigens are identified causes for both false-positive and false-negative results.[232] Widal test titers may be more useful in children with typhoid who are living in a nonendemic area. Interpretation of Widal test results is aided by information about seropositivity in the population to which the patient belongs.[62,313] Some centers have found the Widal test helpful when it is used with locally determined cutoff points.[64,238] Only under unfavorable circumstances when no confirmatory microbiologic test result is available, the Widal test could be used to diagnose typhoid fever, but underscoring this approach is not to be encouraged.[232] Various diagnostic kits, including serologic tests such as passive hemagglutination, passive bacterial agglutination, latex particle agglutination slide tests, counterimmunoelectrophoresis, radioimmunoassay, and enzyme-linked immunosorbent assay with use of monoclonal antibodies, have been developed.[154] These commercial assays (i.e., Typhidot, Typhidot-M, and Tubex) have not proved to be sufficiently robust in large-scale evaluations in community settings.[30] Molecular techniques used primarily in epidemiologic studies include DNA hybridization studies, phage typing, chromosome analysis, and plasmid analysis. A salivary anti–*Salmonella typhi* lipopolysaccharide IgA enzyme-linked immunosorbent assay (ELISA) test for diagnosis of typhoid fever in children has shown promising results, but more research is needed.[343]

DIFFERENTIAL DIAGNOSIS

Salmonella gastroenteritis cannot be distinguished clinically from other infectious causes of acute diarrhea reliably, although history and epidemiology sometimes may suggest an etiologic agent. Bloody diarrhea with mucus can be caused by *Salmonella*, *Shigella*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, *Campylobacter* spp., *Yersinia enterocolitica*, *Clostridium difficile*, *Trichuris trichiura*, and *Entamoeba histolytica*. Watery diarrhea may be caused by rotavirus or other viral enteropathogens or enterotoxin-producing bacterial pathogens. When abdominal pain and tenderness are severe, the differential diagnosis includes appendicitis, perforated viscus, and mesenteric adenitis.

Enteric fever can mimic other infections of the reticuloendothelial system,[31] including Epstein-Barr virus infection, disseminated histoplasmosis, tuberculosis, ehrlichiosis, brucellosis, leptospirosis, tularemia, plague, malaria, systemic *Bartonella henselae* infection, and typhus. Noninfectious illnesses with prolonged fever that sometimes can be confused with typhoid include juvenile rheumatoid arthritis and other collagen vascular diseases, Kawasaki syndrome, and lymphomas. An early diagnosis often is difficult to establish because the findings are nonspecific. Findings that are particularly helpful in discriminating typhoid fever from other prolonged febrile illnesses include severe cough and chest pain (more

TABLE 111-7 **Antibiotics Commonly Used in the Treatment of *Salmonella* Infections**

Drug	Dose	Comments
Ciprofloxacin	10-20 mg/kg/day in two doses PO or IV	First-line therapy (*)
Ceftriaxone	50-100 mg/kg/day in one or two doses IM or IV	First-line therapy
Cefotaxime	100-200 mg/kg/day in three doses IM or IV	First-line therapy
Cefixime	10-20 mg/kg/day in one or two doses PO	Alternative therapy
Azithromycin	8-12 mg/kg/day in one dose PO	Alternative therapy
Chloramphenicol	50-75 mg/kg/day in four doses PO	High frequency of resistance; use only for susceptible strains
Ampicillin	200 mg/kg/day in four doses PO, IM, or IV	High frequency of resistance; use only for susceptible strains
TMP-SMX	10 mg/kg/day TMP, 50 mg/kg/day SMX in two doses PO or IV	High frequency of resistance; use only for susceptible strains

*Non-FDA approved in children younger than 18 years old, while current expert opinion agrees in recommending this agent as an effective therapy for regions with susceptible *Salmonella* strains and especially for severe infections.
TMP-SMX, Trimethoprim-sulfamethoxazole.

typical of lobar pneumonia), diarrhea with grossly obvious blood (more typical of dysentery), acute onset of chills (more typical of malaria), and marked lower abdominal pain early in the febrile illness (more typical of bacillary dysentery, *Y. enterocolitica* infection, and salpingitis). For patients in countries where typhoid is not endemic, a history of travel is crucial. In endemic developing countries, the widely variable false-positive and false-negative results of the Widal test complicate the differential diagnosis workup, favoring the misuse of antimicrobials.[241] *Salmonella* infections could be a cause of fever of unknown origin, especially in developing countries.[61]

TREATMENT

For children with salmonellosis for whom antibiotic treatment is appropriate, the interpretation of antimicrobial susceptibility studies is important. Drugs such as aminoglycosides, polymyxins, tetracyclines, and first-generation and second-generation cephalosporins (e.g., cephalothin, cefazolin, cefuroxime, cefamandole) have a poor clinical track record, despite apparent in vitro susceptibility. Table 111-7 shows the drugs that typically are useful in treatment of children with *Salmonella* infections. The emergence of *S.* ser. Typhimurium DT104 in the United States has led to a dramatic increase in multidrug-resistant (i.e., ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline) organisms.[121]

Gastroenteritis

As with all forms of gastroenteritis, fluid and electrolyte replacement and maintenance are the first objective of management. For most patients, oral rehydration is all that is necessary to treat *Salmonella* gastroenteritis. Generally, *Salmonella* gastroenteritis should not be treated with antibiotics because these agents do not shorten the course of illness* but prolong excretion of *Salmonella*.†

*References 15, 17, 57, 58, 166, 194, 227, 244, 275.
†References 15, 17, 85, 166, 227, 244.

Salmonella serotypes typically have been grouped together for these treatment studies, however, as though they were all the same organism. Given the variability in expression of virulence genes, whether treatment may be useful for some serotypes that possess particular virulence traits remains an open question.

Exceptions to the generalization that *Salmonella* gastroenteritis should not be treated include children at high risk for developing complications, including children with underlying diseases or receiving therapies that impair host defenses. Examples of children who probably ought to be given antibiotics are infants 6 months or younger; children with AIDS or malignant diseases; those splenectomized; children with primary immunodeficiencies; children with chronic hepatopathy; and children with hemolytic anemias, particularly sickle-cell anemia. Treatment of these patients is debatable; the data from neonates suggest that antibiotics make little difference in the course.[1,95,166,260,300] Because the risk for development of bacteremia is high, however, antibiotics likely will continue to be used in such settings. Bacteremia occurs in a small fraction of infections; therefore, proving the concept is impossible without conducting a massive placebo-controlled clinical trial. When treatment is given, probably 5 days or fewer of antibiotics is indicated, barring complications. Ciprofloxacin or a third-generation cephalosporin (i.e., ceftriaxone or cefotaxime) are recommended in preference to former suggestions in favor of ampicillin or amoxicillin.[38] Parenteral therapy with a third-generation cephalosporin or fluoroquinolone has been related to reductions in duration of fever and hospitalization in one retrospective study of children with more severe gastroenteritis.[312]

Extraintestinal Infections

Any child who appears to be sufficiently toxic that bacteremia is suspected also should be started on antibiotic treatment until blood cultures exclude the diagnosis. For children with bacteremic nontyphoidal *Salmonella* and focal extraintestinal complications, a third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) or fluoroquinolone is an appropriate choice. If the patient seems

TABLE 111-8 **Recommended Antibiotic Treatment of Typhoid Fever**

Susceptibility	Antibiotic	Daily Dose (mg/kg)	Days
Full susceptible	Chloramphenicol *or*	50-75	14-21
	Amoxicillin *or*	75-100	14
	Trimethoprim-sulfamethoxazole *or*	8/40	14
	Third-generation cephalosporin (e.g., cefixime) *or*	15-20	7-10
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	30	7-10
Multidrug-resistant	Azithromycin	20	5-7
	Third-generation cephalosporin (e.g., cefixime) *or*	15-20	7-10
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	30	7-10
Quinolone-resistant	Azithromycin *or*	20	5-7

	Parenteral third-generation cephalosporin (e.g., ceftriaxone) *or*	80	7-10
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	30	7-10

to have a life-threatening infection, ampicillin and chloramphenicol should be used only if evidence exists that the pathogen is not resistant to ampicillin or chloramphenicol and that no meningitis or related involvement is suspected. Children at high risk for having recurrence of bacteremia (children with congenital or acquired immunodeficiencies, such as AIDS) may require a third-generation cephalosporin or a fluoroquinolone to achieve cure.[68,146] Frequent recurrences of life-threatening infection sometimes necessitate use of prolonged or life-long maintenance therapy with an oral agent, after controlling the episode with prolonged combined parenteral therapy guided by antibiogram results.[146]

Apparent recurrent episodes of nontyphoidal salmonellosis in the same child are actually a persistent infection by the same clone in nearly 80 percent of cases[231] and merit evaluation in search of primary or acquired immune deficiencies.

Meningitis should be treated with a third-generation cephalosporin because these agents have good penetration into the CSF; ampicillin and chloramphenicol use is associated with higher relapse rates and lower cure rates.[169,235] Meningitis must be treated for at least 4 weeks; approximately three fourths of patients who have relapses have been treated for 3 weeks or less.[66] *Salmonella* may persist for more than 3 weeks inside CSF mononuclear leukocytes despite negative CSF cultures.[58] Some authors suggest combined antimicrobial therapy with cefotaxime or ceftriaxone plus ciprofloxacin for meningitis.[53,130,235,251] Dexamethasone before or at the time of initiation of antimicrobials aimed to reduce the severity of sequelae of bacterial meningitis in children is recommended by extension to *Salmonella* meningitis by some authors[12,149,339] but available data are very limited to lead to definitive conclusions.[217,218,318] Timely initiation of appropriate active bactericidal antimicrobials and severity of disease on arrival are important determinants of outcome, especially in developing countries.[89] Carbapenems such as imipenem and meropenem have been used with good results in a few cases of *Salmonella* meningitis,[52,235] but risk for seizures with imipenem therapy must be considered.[251] Regarding ceftriaxone effectiveness in contrast to ceftazidime and cefotaxime, data from case series suggest a better response to ceftriaxone, especially compared to ceftazidime.[180]

For other extraintestinal infections in children, the duration of antibiotic treatment usually is 10 to 14 days for bacteremia and 4 to 6 weeks for acute osteomyelitis. Collections of pus should be drained, and for intracranial collections, the total duration of antimicrobial therapy should be extended to 4 to 6 weeks after drainage if this is feasible.[52] Nonaccessible collections in the central nervous system would need more prolonged therapy and complicate outcomes. Schistosomiasis, when present, must be treated to achieve resolution of the coincident *Salmonella* infection.[263]

Typhoid Fever

The response to antibiotics is slow. Fever may persist for many days, even after bacteremia has resolved.[344] The emergence and spread of MDRST since 1989, defined as combined resistance to chloramphenicol, TMP-SMX, and ampicillin,[344] caused a shift in empirical therapy from once first-line drugs to a fluoroquinolone; a third-generation cephalosporin, such as ceftriaxone; or azithromycin in children (Table 111-8). MDRST is particularly common in the Indian subcontinent, Southeast Asia, and Africa, and resistance to ciprofloxacin is increasing.[63,267]

In the United States, MDRST has been less problematic than it is elsewhere, but resistance to ampicillin, chloramphenicol, and TMP-SMX has continuously increased since the 1990s.[3,191,274] Currently, most *S.* ser. Typhi isolates are still sensitive to ceftriaxone and ciprofloxacin, although nalidixic acid–resistant isolates are common in travelers returning from the Indian subcontinent.[3,191] Such strains respond poorly to fluoroquinolones, with a 30-fold chance of requiring retreatment.[326] When the patient has a history of recent travel to an area with MDRST or of contact with an individual returning from such an area, the choice of empirical treatment should take this information into account. New minimum inhibitory concentration (MIC) breakpoints have been established for determination of *Salmonella* susceptibility, intermediate sensitivity, or resistance against ciprofloxacin.[151] As a result, MICs of 1 μg/mL or

less but 0.06 μg/mL or greater are associated with delayed antimicrobial responses to ciprofloxacin or even to clinical failure.[151] Third-generation cephalosporins are effective against MDRST* and appropriate for children in such circumstances. Although older small trials in adults suggested shorter courses could be comparable to longer courses of treatment, caution is granted for decisions on treatment duration for children given to low quality of evidence and ever-changing susceptibility patterns over time.[336] For MDRST in children, ceftriaxone given at 65 mg/kg/day in children was associated with relapses with short-course therapy (7 days) in contrast to 14 days of therapy.[32]

Current evidence supports ceftriaxone, cefotaxime, azithromycin, and fluoroquinolones as the most effective drugs for the treatment of typhoid fever.[11,38,336] Fluoroquinolone drugs have proved safe in all age groups, are rapidly effective, and are associated with lower rates of stool carriage than traditional first-line drugs. The three main issues regarding the use of fluoroquinolones are (1) the potential for toxic effects in children, (2) the cost, and (3) the potential emergence of resistance.[240] In preclinical testing, the fluoroquinolones damaged the articular cartilage of young beagles. A considerable body of evidence exists for supporting safety of fluoroquinolones from the long-term use of these drugs in children with cystic fibrosis and from short-term use to treat typhoid fever and dysentery in children. Availability of generic fluoroquinolones in many developing countries favored the emergence of fluoroquinolone resistance resulting from its misuse, which turn as the greatest limitation on their use.[239]

In the developed world, described concerns about toxicity of fluoroquinolones in children have limited their use to situations of MDRST infections with confirmed resistance to all of the usual antibiotics but sensitive to a fluoroquinolone. If a fluoroquinolone is used, ciprofloxacin or ofloxacin is preferred because of better oral bioavailability. Ciprofloxacin 15 mg/kg/dose twice daily for 7 to 10 days in children causes defervescence in an average of 4.2 days with infrequent relapses, even with MDRST.[9] Children with MDRST who have been treated with ciprofloxacin 10 mg/kg/day became afebrile in 3.3 days, and 94 percent achieved clinical cure, with no relapses or carriers detected on follow-up.[93] Ofloxacin is associated with more rapid defervescence and better cure rates than cefixime.[46] Very short courses of ofloxacin (2 or 3 days) may be followed by relapse.[229,321]

Fluoroquinolone treatment for typhoid fever produced lower relapses (relative risk [RR], 0.04 to 0.52) and length of hospital stay (−3.53 to −1.62 days) in contrast to chloramphenicol.[307] Clinical failure (RR, 0.01 to 0.54) and microbiologic failure (RR, 0.03 to 0.64) were reduced for fluoroquinolones in contrast to β-lactam antibiotics treatment.[307] Fluoroquinolones performed better than third-generation cephalosporins leading to lower clinical failures and duration of hospital stay.[307]

Other agents have been described that occasionally may be useful. Furazolidone 7.5 mg/kg/day is nearly as effective as is chloramphenicol in strains susceptible to both drugs (86% vs. 90% cure).[66] Despite low serum levels, azithromycin seems to be equivalent to chloramphenicol or ciprofloxacin; the high intracellular concentration in macrophages (>100 times serum levels) of azithromycin presumably accounts for its efficacy.[45,120] When MDRST is resistant to nalidixic acid, azithromycin is more effective than ofloxacin, resulting in faster resolution of fever and very effective control of fecal carriage in contrast to ofloxacin and even to combined therapy of azithromycin with ofloxacin.[54,240]

A 5-day course of oral azithromycin 20 mg/kg/day (maximum 1000 mg/day) is as effective as intravenous ceftriaxone 75 mg/kg/day (maximum 2.5 g/day for 5 days).[111] Various nonantimicrobial measures should be considered as part of the management of *S.* ser. Typhi infections.

No good level of evidence exists to establish superiority of fluoroquinolones over first-line antibiotics for typhoid fever specifically in children, but fluoroquinolones are suggested at this time as first-line therapy. Because of the high level of resistance in some regions of the world, the World Health Organization recommendations for second-line therapy options include third-generation cephalosporins and azithromycin.[336]

Dexamethasone, although potentially increasing the relapse rate,[69] is indicated for patients with severe typhoid fever with delirium, stupor, shock, or coma; the dose is 3 mg/kg initially and then eight doses of 1 mg/kg every 6 hours for 48 hours. This therapy reduces mortality rates from 35 to 55 percent to 10 percent.[142,252] Parenteral fluoroquinolones are probably the antibiotic of choice for severe infections, but no randomized trials of such treatment have been performed.[93] Antipyretics were thought at one time to be dangerous in typhoid fever[87]; whether this concern is correct is doubtful on the basis of more recent experience.[230]

Intestinal hemorrhage or perforation during enteric fever generally is considered to be an indication for surgical intervention.[33,44,118,185] Resection of 10 cm of intestine proximal and distal to the perforation seems to improve outcome in contrast to other surgical approaches.[18] Antibiotic coverage should be broadened to include anaerobes and gram-negative enterics when perforation occurs.[33]

Chronic Carriers

Generally, patients who are not food handlers probably should not be cultured or given special treatment after having a bout of gastroenteritis caused by a nontyphoidal *Salmonella* strain. Carriers of *S.* ser. typhi should be decolonized to decrease the risk to close contacts. Carriers who have a normal gallbladder can be treated with oral ciprofloxacin or norfloxacin for 4 weeks; these drugs concentrate highly in bile.[11] If oral fluoroquinolone therapy is not tolerated, then high-dose intravenous ampicillin for 4 weeks could be indicated.[11] Other options are oral ampicillin or amoxicillin combined with probenecid for 6 weeks. Chronic carriers who cannot be decolonized are treated with cholecystectomy if cholelithiasis or cholecystitis is present; these patients should receive

*References 98, 154, 169, 209, 220, 237, 290, 309.

ampicillin intravenously for 7 to 10 days before and 30 days after cholecystectomy.

PREVENTION

Public Health Measures

Recognition of an increased frequency of human infections with an unusual serotype should be followed by an epidemiologic investigation aimed at detecting the source and vehicle. Intervention to stop such outbreaks then can be attempted. Judicious use of antibiotics in dairy and livestock animals,[144] careful food processing and storage, and proper preparation of foods are helpful in decreasing transmission of infection. Appropriate sewage disposal, assurance of a safe water supply, prevention of sale of pet turtles, inspection of cosmetics for contamination, and adequate cleaning of medical equipment are important public health strategies. Families with small children should be informed of the risks associated with pet reptiles and encouraged to avoid such unnecessary risks.

Personal Hygienic Measures

Person-to-person spread can be decreased by hand washing after defecating or changing diapers, frequent hand washing during preparation of foods that might be contaminated (e.g., meat), and excluding of infected individuals from food-handling tasks.

Infection Control

Hospitalized children with *Salmonella* gastroenteritis should be isolated (enteric precautions) until stool cultures are negative. Children with extraintestinal infections should be isolated until stool studies exclude intestinal infection or colonization.

Nursery Outbreaks

Neonatal *Salmonella* infection outbreaks should be investigated to determine the source. Cultures of fomites sometimes reveal a removable focus. Neonates and staff members caring for them should be cohorted during outbreaks, with use of enteric precautions in dealing with infants who are excreting the organism. Surveillance cultures should be done on feces of not only sick infants but also well infants to cohort more appropriately. With current early postpartum discharge policies, reporting *Salmonella* infections in infants is important in detecting outbreaks. Isolation and cohorting can be effective in controlling such outbreaks.[259]

Breast-Feeding

In the developing world, breast-feeding is key in prevention because human milk contains secretory IgA and other factors that protect infants from *Salmonella* spp.[35,101,110,247,248] In a case-control study conducted in the United States, breast-feeding was found also to have a strong protective effect against sporadic *Salmonella* infections.[268] Pediatric health care providers and community education programs should encourage mothers to breast-feed.

Vaccination

Several vaccines have been developed for typhoid fever. Vaccination of children is indicated when the risk for development of typhoid fever is high (e.g., living with a chronic carrier or in an endemic area) but probably is underused.[306] Two vaccines are available: (1) an oral live attenuated Ty21a vaccine (Vivotif Berna) and (2) a parenteral purified Vi capsular polysaccharide vaccine (Typhim Vi).[171,249]

The Ty21a vaccine has been evaluated in liquid and capsule forms. Ty21a oral vaccine is well tolerated; abdominal pain, nausea, vomiting, and rashes occur rarely. The form licensed in the United States is an enteric-coated capsule preparation meant to be given in four separate doses on alternate days taken 1 hour before meals. It is not recommended for children younger than 6 years of age. The four doses should be completed 1 week before potential exposure.[11] Revaccination with the entire four-dose series is recommended every 5 to 7 years in high-risk settings. Because the Ty21a oral vaccine is a live-attenuated *Salmonella*, it should not be used in immunocompromised hosts or in individuals taking antibiotics at the time of receiving vaccination.[48] The antimalarial mefloquine inhibits growth of the attenuated organism, and vaccination should be delayed for 24 hours after its use. Malaria prophylaxis with atovaquone and proguanil does not interfere with immune response to Ty21a.[100]

Several large field trials suggest that the Vi capsular vaccine as a single 25-μg dose (0.5 mL) has an efficacy of 55 percent and 75 percent in adults and children older than 5 years.[2,249] Although fever, malaise, local pain, and tenderness occur with this vaccine, it has two major advantages over the Ty21a oral vaccines: It does not require refrigeration, and only a single dose is required for protection and then repeated every 3 years.[337] It may be used in children 2 years of age. Vaccination must occur at least 2 weeks before exposure.[11]

A parenteral Vi vaccine conjugated with tetanus toxoid is licensed and produced in India (Peda Typh). The first dose is advised for subjects older than 2 years of age, followed by a second dose at 4- to 8-week intervals, and then by a booster every 10 years.[182] Several vaccine producers from Asia, Russia, and Cuba manufacture local-use parenteral polysaccharide Vi vaccines.[182] Typhoid vaccination is recommended additionally for curtailing typhoid fever outbreaks.[337]

PROGNOSIS

Salmonella gastroenteritis usually is a self-limited disease in the normal host, although chronic diarrhea sometimes develops after an acute episode. Extraintestinal focal infections with nontyphoidal *Salmonella* strains are difficult to cure, particularly if they involve the meninges or occur in compromised hosts. *Salmonella* spp. meningitis may relapse if the course of treatment is too short.

Likewise, bacteremia and focal infection recur after treatment in severely compromised hosts, particularly patients with AIDS. Relapse after typhoid fever has long been recognized as a risk.

CHAPTER 112

PLAGUE (*YERSINIA PESTIS*)

Gary D. Overturf

HISTORY AND EPIDEMIOLOGY

Yersinia pestis has been responsible for the most devastating epidemics in human history. Plague was first mentioned in 1320 BCE in the Old Testament in I Samuel, chapters 5 and 6. The first of three pandemics was heralded by the Justinian plague in northern Africa and the Mediterranean (541-700).[48] The second pandemic occurred in Sicily in 1346; also in that year, plague appeared during the siege of the city of Kaffa in the Crimea, thereafter spreading throughout most of Europe, where it became known as the "Black Death," having been introduced by accompanying rodent populations from China along Asian-European trade routes. One third of the population of Europe died in its aftermath. Between the 14th and 20th centuries, plague occurred throughout Europe and Russia, with resultant frequent outbreaks.[43]

In 1894, Yersin and Kitasato, working independently, first described the plague bacillus while investigating plague that spread from mainland China to Hong Kong,[47] and the role played by rats and fleas in the spread of the disease was defined.[61] In 1900, plague was introduced into San Francisco by rats aboard ships docking there. The disease spread to ground squirrels and then to other wild animals of the American Southwest.[46] In 1943, effective antibiotics against *Y. pestis* became available. Although antibiotics have been effective in the treatment and prophylaxis of plague, plasmid-borne antibiotic resistance is increasingly being noted.[19] The potential for aerosolized *Y. pestis* as a biologic weapon has led to renewed interest in the understanding and study of this organism.[28]

Plague is now a worldwide disease. The World Health Organization reported 38,359 human cases of plague from 1989 to 2003 that resulted in 2,845 deaths. Approximately 80 percent of the cases occurred in Africa with endemic sites in east Africa and Madagascar; 15 percent were reported from Asia, including China, southeast Asia, and India; and 5 percent occurred in the Americas.[63] Plague remains endemic in the American Southwest, with more than 80 percent of cases occurring in New Mexico, Arizona, and Colorado and approximately 10 percent in California[11,27]; plague, however, occurs in rodent populations of 17 contiguous states west of the 100th meridian.[19,20]

BACTERIOLOGY

Y. pestis is in the family Enterobacteriaceae and is one of 14 *Yersinia* spp. It is a small, pleomorphic, nonmotile, gram-negative bacillus and is closely related to one of the three pathogenic representatives of the genus, *Yersinia pseudotuberculosis*.[49,57,60] With Wayson, Giemsa, and Gram stains, the bacillus takes on bipolar or "safety pin" morphologic features.[17] *Y. pestis* grows on blood, chocolate, and MacConkey agars at temperatures ranging from 0°C to 40°C (32°F to 104°F); the optimal temperature is 28°C (82.4°F). On first isolation at 35°C (95°F) on 5 percent blood agar, the colonies are pinpoint in size, growing to 1 to 2 mm after 2 days. They are nonhemolytic on 5 percent sheep blood agar.[60]

Depending on the clinical nature of the disease, blood cultures, sputum samples, or aspirates of enlarged nodes
